Abstract: [NH₃(CH₂)₅NH₃]MnCl₄ crystals are grown via slow evaporation, and the crystal undergoes a phase transition at 298 K (T_C) according to differential scanning calorimetry, and the structures determined via X-ray diffraction at 173 and 333 K are orthorhombic systems in the space group Imma. These results differed slightly from those previously reported, and the reasons for this are analyzed. The thermal stability is relatively high, with a thermal decomposition temperature of approximately 570 K. The ¹H spin-lattice relaxation times t₁ρ exhibited very large variations, as indicated by the large thermal displacement around the ¹H atoms, suggesting energy transfer at ~T_C, even if no structural changes occurred. The influences of the chemical shifts of ¹H of NH₃ and short t₁ρ of C1 adjacent to NH₃ in cation are insignificant, indicating a minor change in the N−H···Cl hydrogen bond related to the coordination geometry of the MnCl₄ octahedron. These properties will be make it a potential application for eco-friendly solar cells.

Keywords: crystal structure; organic–inorganic hybrid; [NH₃(CH₂)₅NH₃]MnCl₄; phase transition; nuclear magnetic resonance; thermodynamic properties

1. Introduction

Hybrid perovskite compounds are of scientific interest because of the diversity of their crystal structures, which govern their structural dynamics and ferroelastic and thermodynamic properties. In addition, ferroelasticity is commonly observed in compounds with perovskite crystal structures, and the ferroelastic twin domains in organic–inorganic hybrid perovskites attract much attention [1–6]. The organic cation of the hybrid material contributes to properties such as structural flexibility and optical characteristics, whereas the inorganic anion is responsible for the thermal and mechanical properties [7,8]. Moreover, the fabrication of hybrid perovskites was recently reported as a major challenge in the context of developing ferroelastic semiconductors [9]. Furthermore, successful hybrid perovskite ferroelectric performances render hybrid perovskites suitable candidates for use in flexible and wearable devices [10,11]. Additionally, solar cells based on CH₃NH₃PbX₃ (X = Cl, Br, or I) organic–inorganic hybrid compounds recently attracted interest. However, perovskites containing Pb are toxic and decompose in humid air, and thus, developing alternative green hybrid perovskite solar cells is necessary [4–6,12–16]. Hence, detailed characterizations of perovskite structures and the dynamics of novel organic–inorganic hybrid compounds [NH₃(CH₂)₅NH₃]MX₄ (n = 2, 3, 4, . . . , MII is a transition metal, such as Mn, Fe, or Cu, and X is a halogen ion), which crystallize in perovskite-type layer structures in various configurations, are increasingly necessary due to their potential applications as green alternatives. The diammonium hybrid perovskites [NH₃(CH₂)₅NH₃]MX₄, with one-dimensional (0D) and two-dimensional (2D) structures, have been extensively investigated [17–30]. In the case of B = Mn, Cu, and Cd, the crystal structures consist of an alternate octahedrally coordinated (BX₆)²⁻ and organic cations. In the case of B = Co and
Zn, isolated tetrahedral \((BX_4)^{2-}\) is coordinated between the organic cations \([31,32]\). These 2D hybrid perovskite types have various potential applications in electrochemical devices such as chemical sensors, supercapacitors, batteries, and solar cells \([17,24,25,33]\).

Layered 2D hybrid perovskite \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) crystals \((n = 5, M = \text{Mn}, \text{and } X = \text{Cl})\) comprise organic and inorganic ions. The organic \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]^{2+}\) cations and inorganic \([\text{MnCl}_4]^{2-}\) anions are alternately stacked along the longest axis, with the inorganic layer extended via corner-shared octahedra. The organic and inorganic layers are interconnected by \(\text{N} - \text{H} \cdot \cdot \cdot \text{Cl}\) hydrogen bonds \([23]\). The phase transition associated with the order–disorder transition between two orthorhombic phases is from \(\text{Pnma}\) to \(\text{Imma}\) at 299.6 K \((= \text{phase transition temperature } T_C)\) \([31]\). The lattice constants at 298 K reported by Mondal et al. \([23]\) are \(a = 7.1742\) Å, \(b = 7.3817\) Å, \(c = 23.9650\) Å, and \(Z = 4\). The crystal structure at 298 K is shown in Figure 1 (CCDC 1401387) \([23]\), with each layer of alkylenediamonium chains inserted between two infinite sheets of corner-sharing \(\text{MnCl}_6\) octahedra.

![Figure 1. Orthorhombic structure of a \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) crystal at 298 K \([23]\).](image)

Research regarding \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) was initially published by Arend et al. \([34,35]\), mainly as research reports regarding the crystal structure and \(T_C\) of 299.6 K based on the heat capacity. Based on recent results, Mondal et al. \([23]\) studied the crystallographic characteristics of this crystal, with Lv et al. \([36]\) reporting the dielectric and photoluminescence characteristics.

In this study, \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) single crystals were grown using an aqueous solution-based method, and \(T_C\) was confirmed using differential scanning calorimetry (DSC). In addition, the structures of the crystals below \(T_C\) and above \(T_C\) were confirmed using single-crystal X-ray diffraction (XRD). The thermodynamic properties were investigated as a function of temperature. Finally, the structural dynamics of the \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]^{2+}\) cation at \(\sim T_C\) were analyzed using nuclear magnetic resonance (NMR) chemical shifts and spin-lattice relaxation times \(t_1\). The physicochemical properties of \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) without structural changes at \(\sim T_C\) should render its use in proton conductors viable.

2. Materials and Methods

Single crystals of perovskite-type \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) were grown via slow evaporation from an aqueous solution containing \(\text{NH}_2(\text{CH}_2)_5\text{NH}_2\cdot 2\text{HCl} (98\%, \text{Sigma-Aldrich, St. Louis, MO, USA})\) and \(\text{MnCl}_2 (98\%, \text{Sigma-Aldrich})\). The mixture was stirred and heated,
the resulting solution was filtered, and light-yellow single crystals were obtained after five weeks in a constant-temperature bath at 300 K.

Fourier transform infrared (FT-IR) spectra were measured between 4000 and 500 cm\(^{-1}\) using an L1600300 spectrometer (PerkinElmer, Waltham, MA, USA) and compressed KBr pellets.

DSC (DSC 25, TA Instruments, New Castle, DE, USA) was performed to observe the structural phase transitions by heating in the temperature range 200–480 K at 10 K min\(^{-1}\) under \(N_2\) gas. Thermogravimetric analysis (TGA) was performed using a thermogravimetric analyzer (TA Instruments) in the temperature range 300–870 K at the same heating rate.

The lattice parameters at various temperatures were determined via single-crystal XRD at the Western Seoul Center of the Korea Basic Science Institute. A crystal was lifted in paratone oil and mounted in a D8 Venture diffractometer (Bruker, Billerica, MA, USA) equipped with a Mo-K\(\alpha\) radiation source, PHOTON III M14 detector (Bruker), and a nitrogen cold atmosphere (\(-50 \, ^\circ\text{C}\)). Data collection and integration were performed using SMART APEX3 (Bruker, 2016) and SAINT (Bruker, 2016), and absorption correction was performed using a multiscan method implemented in SADABS (Bruker, 2002). The structure was analyzed and refined via the full-matrix least-squares method on \(F^2\) using SHELXTL (University of Göttingen, Göttingen, Germany).

In order to check whether the peak obtained from the DSC result is \(T_C\) or a melting temperature \(T_m\), it was observed using a polarizing optical microscope (Carl Zeiss, Oberkochen, Germany) with a THMS600 heating stage (Linkam, Salfords, UK) at an appropriate temperature for a single crystal.

NMR spectroscopy of the [NH\(_3\)(CH\(_2\))\(_5\)NH\(_3\)]MnCl\(_4\) crystals was conducted using a 400 MHz Avance II+ solid NMR spectrometer (Bruker) with a 4 mm magic angle spinning (MAS) probe (Western Seoul Center, KBSI). \(^1\text{H}\) and \(^{13}\text{C}\) MAS NMR spectra were recorded at Larmor frequencies of 400.13 and 100.61 MHz, respectively. The MAS speed used to minimize the spinning sideband overlap was 10 kHz, and NMR chemical shifts were calibrated using tetramethylsilane (TMS) as the standard. The \(^1\text{H}\) and \(^{13}\text{C}\) \(t_{1\rho}\) values were obtained via the \(\pi/2 - \tau\) sequence method by changing the spin-locking pulses—the \(\pi/2\) pulse widths for \(^1\text{H}\) and \(^{13}\text{C}\) were \(~3.7\ \mu\text{s}\). The temperature variation was determined by adjusting the heater current and \(N_2\) gas flow.

3. Results

3.1. FT-IR Spectroscopy

Figure 2 shows the FT-IR spectrum of the [NH\(_3\)(CH\(_2\))\(_5\)NH\(_3\)]MnCl\(_4\) crystal at 300 K in the range 4000–500 cm\(^{-1}\). The bands at 3122 and 3043 cm\(^{-1}\) are characteristic of the C–H bonds of the protonated ligand, and the band at 2934 cm\(^{-1}\) suggests the presence of N–H···Cl hydrogen bonds. The band at 1568 cm\(^{-1}\) is due to the asymmetric mode of NH\(_3\), whereas the strong band at 1488 cm\(^{-1}\) is assigned to the symmetric deformation mode of NH\(_3\). Finally, the bands close to 1169 and 980 cm\(^{-1}\) are assigned to the C–N and C–C modes, respectively. The observed FT-IR bands are consistent with those previously reported [23].

3.2. Phase Transition and Crystal Structure

The DSC thermogram measured at a heating rate of 10 K min\(^{-1}\) under an \(N_2\) atmosphere is shown in Figure 3. An endothermic peak is observed at 298 K, and the \(T_C\) of 298 K is consistent with that reported previously [36]. The enthalpy for the phase transition was 689 J/mol.
The structures obtained via single-crystal XRD are identical to the orthorhombic structures below $T_C$ and above $T_C$. The lattice constants at 173 K ($< T_C$) are $a = 24.1756$ Å, $b = 7.1583$ Å, and $c = 7.3898$ Å in the space group Imma, whereas those at 333 K ($> T_C$) are $a = 23.9162$ Å, $b = 7.1877$ Å, and $c = 7.3314$ Å in the space group Imma. Table 1 shows the single-crystal data collection and refinement parameters of the [NH$_3$(CH$_2$)$_5$NH$_3$]MnCl$_4$ crystal at 173 and 333 K, and the atomic numbering scheme and thermal ellipsoids of the H atoms are shown in Figure 4. The Mn atom is coordinated to six Cl atoms, forming an almost regular octahedron, MnCl$_6$, and the six N-linked hydrogen atoms in one formula unit form N–H⋯Cl hydrogen bonds. The lattice constants as functions of temperature are shown in Figure 5. The lattice constants do not change at $\sim T_C$, and it does not appear to be significantly related to the $T_C$. The detailed results of XRD of the crystal structure are shown in the Supplementary Information S1 and S2.
Table 1. Crystal data and structure refinement for \([\text{NH}_3(\text{CH}_2)_3\text{NH}_3]\text{MnCl}_4\) at 173 K and 330 K. The full data are available in the CIF files.

Figure 4. Thermal ellipsoid plot (50% probability) for structure of \([\text{NH}_3(\text{CH}_2)_3\text{NH}_3]\text{MnCl}_4\) at 300 K.

Figure 5. Single-crystal XRD parameters of a \([\text{NH}_3(\text{CH}_2)_3\text{NH}_3]\text{MnCl}_4\) crystal at 173, 280, 300 and 333 K.
3.3. Thermodynamic Properties

To determine whether the endothermic peaks were related to phase transitions or decomposition, TGA and differential thermal analysis (DTA) were performed at the same heating rate as that used during DSC. The TGA and DTA thermograms shown in Figure 6 reveal that the crystals are virtually stable up to approximately 570 K. The molecular weight of $[\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4$ decreases with increasing temperature above 570 K, and the amount of residue based on the total molecular weight is obtained using Equation (1) [37,38]:

\[
\text{Residue: } [\text{NH}_2(\text{CH}_2)_5\text{NH}_2\cdot\text{HCl}]\text{MnCl}_2 (s)/[\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4 = 87.88% \tag{1}
\]

The temperature at which mass loss commences, based on the TGA thermogram, is approximately 570 K. Therefore, 570 K is the partial thermal decomposition temperature $T_d$. Mass losses of approximately 12% and 24% close to 617 and 630 K may be attributed to the loss of HCl and 2HCl, respectively, as shown in Figure 6. The molecular weight of the crystal decreases sharply between 600 and 700 K, with a mass loss of 50% at approximately 700 K.

To verify the results of TGA and DSC, a single crystal was observed using a polarizing optical microscope while varying the temperature. At 300 K, the crystal is transparent.

![Figure 6. Thermogravimetric analysis and differential thermal analysis curves of $[\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4$ (Inset: Changes in crystal by optical polarizing microscopy at (a) 300 K and (b) 617 K).](image-url)
and light yellow, as shown in Figure 6a. The crystal turns slightly opaque at ~580 K due to partial thermal decomposition. Upon heating further to 617 K, HCl is eliminated, the crystal turns brown, and the surface also appears to melt slightly, as shown in Figure 6b. Based on the results of DSC, TGA, and polarizing microscopy, \( T_C = 298 \) K, as shown in the DSC, whereas \( T_d = 570 \) K.

3.4. \(^1\)H and \(^{13}\)C NMR Chemical Shifts

The \(^1\)H MAS NMR spectra of the \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) crystals recorded at \( \sim T_C \) are shown in Figure 7. The observed resonance lines at low temperatures are asymmetric because of the overlap of the signals representing \( \text{NH}_3 \) and \( \text{CH}_2 \). The linewidths A and B on the left- and right-hand sides of the half-maximum shown in Figure 7 are not equal. Above 300 K, the \( \text{NH}_3 \) and \( \text{CH}_2 \) signals are resolved, and the respective chemical shifts of the resonance lines of \( \text{NH}_3 \) and \( \text{CH}_2 \) are observed at 9.29 and 2.89 ppm. The spinning sidebands are marked with “+” and “o” to represent \(^1\)H in \( \text{NH}_3 \) and \( \text{CH}_2 \), respectively. The \(^1\)H chemical shifts of \( \text{CH}_2 \) do not vary significantly at \( \sim T_C \), whereas changes in the \(^1\)H chemical shifts of \( \text{NH}_3 \) are observed at \( \sim T_C \). The larger changes in the \(^1\)H NMR chemical shifts of \( \text{NH}_3 \) compared to those in the \(^1\)H NMR chemical shifts of \( \text{CH}_2 \) at \( \sim T_C \) suggest a change in the \( \text{N} - \text{H} \cdots \text{Cl} \) hydrogen bonding between \( \text{Cl} \) around \( \text{Mn} \) and \( \text{H} \) of \( \text{NH}_3 \).

3.5. \(^1\)H and \(^{13}\)C NMR Spin-Lattice Relaxation Times

In addition, the \(^{13}\)C NMR chemical shifts in the MAS NMR spectra of \( \text{CH}_2 \) in \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) were recorded at \( \sim T_C \). The \(^{13}\)C signal of TMS was observed at 38.3 ppm at 300 K, and thus, 38.3 ppm was set as the origin for the \(^{13}\)C chemical shifts. Here, \( \text{C} \) in the \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\) cation is located at the center of the cation, \( \text{C}_1 \) is located adjacent to the \( \text{NH}_3 \) in the cation, and \( \text{C}_2 \) is located between \( \text{C}_1 \) and \( \text{C}_3 \), as shown in the inset of Figure 8. The respective chemical shifts of \( \text{C}_1 \), \( \text{C}_2 \), and \( \text{C}_3 \) at 300 K are observed at 113.44, 88.92, and 70.96 ppm, as shown in Figure 8. The \(^{13}\)C chemical shifts of \( \text{C}_1 \) do not vary significantly at \( \sim T_C \), whereas those of \( \text{C}_2 \) and \( \text{C}_3 \) vary at \( \sim T_C \).

---

**Figure 7.** \(^1\)H NMR chemical shifts of \([\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4\) at 200, 250, 300, 310, 320, and 350 K. + and o are the spinning sidebands.
important experiment for studying the dynamical processes. By studying the relaxation of the nuclei in different environments within the cation, it is possible to obtain a detailed picture of the motions. The $T_{1\rho}$ relaxation parameters are particularly informative since it is directly related to those motions in the low- to mid-kHz frequency range [39–41].

![Figure 8](image.png)

**Figure 8.** $^{13}\text{C}$ NMR chemical shifts of $[\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4$ at 250, 280, 290, 300, and 350 K. * and o are the spinning sidebands.

The $^1\text{H}$ and $^{13}\text{C}$ MAS NMR spectra were acquired at several delay times at each temperature. The relationship between the intensities of the NMR signals and delay time is represented by an exponential function. The magnetization decay rates for protons and carbon are characterized by $t_{1\rho}$ as follows [42,43]:

$$P(\tau)/P(0) = \exp(-\tau/t_{1\rho}),$$

where $P(\tau)$ and $P(0)$ are the NMR signal intensities at $\tau$ and $\tau = 0$, respectively. The $^1\text{H}$ and $^{13}\text{C}$ NMR spectra of $[\text{NH}_3(\text{CH}_2)_5\text{NH}_3]\text{MnCl}_4$ were recorded with various time delays. The decay curves may be represented by a single exponential function, as shown in Equation (2). However, the $^1\text{H}$ $t_{1\rho}$ values of NH$_3$ and CH$_2$ at low temperatures may not be distinguished because of the overlapping $^1\text{H}$ NMR signals. The $^1\text{H}$ $t_{1\rho}$ values depend highly on the temperature, as shown in Figure 9. The $^1\text{H}$ $t_{1\rho}$ values of CH$_2$ and NH$_2$ display significant changes at $\sim T_C$, indicating that the $^1\text{H}$ energy transfer of CH$_2$ and NH$_3$ changes significantly. Moreover, the $^{13}\text{C}$ $t_{1\rho}$ values of C1, C2, and C3 are obtained from the slopes of their recovery traces. The $^{13}\text{C}$ $t_{1\rho}$ values of C1, C2, and C3 at $\sim T_C$ are virtually continuous. Notably, the $t_{1\rho}$ values of C1, which are adjacent to NH$_3$, are the shortest. The low $t_{1\rho}$ values of C1, which are close to the Mn$^{2+}$ ions, are related to the magnetic moments of the Mn$^{2+}$ ions, which are paramagnetic.
4. Discussion

The crystal structures, phase transitions, thermal stabilities, and molecular dynamics of the [NH₃(CH₂)₂NH₃]MnCl₄ crystals were investigated using XRD, DSC, TGA, and NMR spectroscopy. First, we reconfirmed that the structure was an orthorhombic system in the space group Imma at 173 and 330 K, and Table 2 shows our results and those previously reported. Arend et al. suggested the space group as Ima2 or Imma at ~Tₐ [34,35], and Chhor et al. [31] reported that the structure was orthorhombic in the space groups Pnma below Tᵣ and Imma above Tᵣ. According to Lv et al. [36], the space groups below Tᵣ and above Tᵣ were Pnma and Imma, respectively, and Modal et al. [23] reported that the space group at Tᵣ, not below Tᵣ or above Tᵣ, was I2₁₂₁₂₁. In this study, the space group and lattice parameters of the crystal structure differ slightly, and thus, to study the phase transition, an accurate structural analysis is required. Our results are similar to those above Tᵣ reported by Lv et al. [36].

Table 2. Phase transition temperature Tᵣ (K), structure, space group, lattice constants (Å), Z, and measured temperature (K) for [NH₃(CH₂)₂NH₃]MnCl₄ crystal.

Our results showed that the thermal stability was relatively high, with a thermal decomposition temperature of approximately 570 K. The NMR spectra further suggested...
that the energy transfer of $^1$H at $\sim$T$_C$ was very large, as indicated by the large thermal displacement around the $^1$H atoms.

5. Conclusions

As previously reported by other groups, the space groups under T$_C$ were Pnma or I2$_1$2$_1$2$_1$. Thus, we analyzed Pnma and I2$_1$2$_1$2$_1$ by XRD results, but determined to be closer to Imma. Based on the results of XRD, the structures below T$_C$ and above T$_C$ were orthorhombic in the space group Imma. There may be several reasons for the slightly different results. T$_C$ is 298 K, and thus, the temperature required to characterize the structure should be accurately determined. The difference in the single crystal structure may be due to the observed temperature difference, and it is thought that it may be slightly different depending on the crystal growth conditions; a single crystal may be grown into a naturally occurring structure or a single crystal having a new structure depending on temperature, which is one of the growth conditions. For example, the direction of the twin domain wall in the case of BiVO$_4$ having a ferroelastic twin structure was different [44]. The phase transition at 298 K is due to the energy transfer of $^1$H, with no structural change. The influences of the chemical shifts of $^1$H of NH$_3$ and short molecular weight of Cl adjacent to NH$_4$ in the [NH$_3$(CH$_3$)$_2$NH$_3$]MnCl$_4$ crystal were insignificant, indicating a minor change in the N–H···Cl hydrogen bond related to the coordination geometry of the MnCl$_4$ anion. The structural phenomenon revealed by XRD and NMR at $\sim$T$_C$ shows the potential for the realization of solar cells for use in various applications.
