Abstract: Plant invasions are closely related to environmental filtering and biointeractions; however, the variations in invasive plant niches along latitudinal gradients in heterogeneous habitats remain unclear. In this study, we conducted a two-year survey in China spanning 21° N-37° N to explore the niche characteristics of plant species within communities invaded by the amphibious alien weed Alternanthera philoxeroides in both terrestrial and aquatic habitats as well as their latitudinal trends. We found that A. philoxeroides had the greatest niche breadth in the studied communities. The species pairs with the highest niche similarity were A. philoxeroides-Digitaria sanguinalis in terrestrial communities and Cyperus rotundus-Kyllinga brevifolia in aquatic communities. The niche similarity between A. philoxeroides and its accompanying species in terrestrial habitats was significantly higher than that in aquatic habitats (t = 5.954; p < 0.001). The niche breadth of A. *philoxeroides* had no obvious latitudinal trend, while the niche breadth of its accompanying species in the terrestrial community significantly decreased with increasing latitude ( $F_{7,57} = 4.364$ , p = 0.001). In the terrestrial communities, the niche similarity between A. philoxeroides and its accompanying species significantly decreased with increasing latitude ( $F_{7,57} = 3.671$ , p = 0.003), while the niche overlap significantly increased with increasing latitude ( $F_{7,57}$  = 8.916, p < 0.001). However, the aquatic species' niche characteristics had no obvious latitudinal trends. These findings indicated that habitat heterogeneity significantly affected the species' niche characteristics in A. philoxeroides-invaded communities. Environmental filtering at low latitudes allowed the invasive and accompanying species to evolve similar niches, while the cold climate at high latitudes increased the niche overlap between the invader and accompanying species. Our findings are crucial for predicting the dynamics of invasive plant communities under global change and for understanding the mechanisms of species coexistence.

Keywords: Alternanthera philoxeroides; habitat heterogeneity; latitudinal gradient; niche; plant invasions

## 1. Introduction

In the context of global climate change and economic integration, biological invasions are one of the five serious global environmental problems of the 21st century [1,2]. Frequent resource fluctuations and disturbances resulting from human activities have led to increasing plant invasions, causing a dramatic decline in biodiversity and great damage to the structures and functions of ecosystems [3]. Functional differences between native and alien species are crucial factors for accelerating successful plant invasions; invasive plants usually have a higher growth rate and higher photosynthesis, water use efficiency, specific leaf area, nitrogen content and interspecific competitiveness than their native accompanying species [4–7], as well as stronger responses to environmental changes [8–10].

A recent meta-analysis has shown that multiple invasive plants could also have a synergistic invasion effect, resulting in twice the negative effect on neighboring natives than on other alien plants [11]. However, biological invasions and native species diversity often demonstrate positive relationships in large-scale observational studies but are negatively correlated in small-scale experimental studies; this phenomenon is referred to as the invasion paradox [12–14]. Exploring the performance and ecological effect of invasive plants at large spatial scales is helpful for implementing effective invasion prevention and biodiversity protection measures.

A niche represents the utilization degree of various resources by plant species, while niche breadth, niche similarity and niche overlap are important indicators for measuring plant niches; in addition, these factors reflect the role of plant species in communities and their demands for living environments [15,16]. Under conditions with limited resources, species that have similar niches will compete fiercely with each other and cannot stably coexist [17,18]. The expansion of invasive plant populations is usually associated with niche changes, and their niche characteristics are determined by environmental filtering, biointeractions, adaptive evolution and other factors [15,16,19,20]. Many invasive plants have undergone niche shifts and have expanded their climate niches through adaptive evolution and phenotypic plasticity, which is of great benefit for quickly occupying the open niche, and thus facilitates their invasion process [21–23]. In brief, the key to the successful invasion of alien plants is their ability to create 'niche opportunities' through various mechanisms, such as successfully coexisting in native communities through heterogeneous resource use or by increasing their diffusion ability by competing for the same resources with native species [24,25].

Hydrothermal fluctuations caused by latitudinal variations significantly affect the niche changes in invasive plant species. Compared with native plants, invasive plants usually have higher climate tolerance and phenological plasticity, which benefit their ability to form a wide niche breadth to resist climate change [26–29]. Moreover, global warming weakens the biotic resistance of native plant communities at higher latitudes, thus creating favorable niche spaces for invasive plants in those regions [30]. The latitude–niche breadth hypothesis predicts that tropical species evolve into narrower niches due to weak seasonality and environmental variability at low latitudes, while frequent climate changes at high latitudes promote the evolution of wider niches [31]. Rapoport's ecogeographic rules also propose that the distribution ranges of species shrink with decreasing latitude, and intense interspecific competition at low latitudes reduces species niche breadth, which negatively correlates with latitude [32,33]. The germination niche breadth and climate niche breadth of some invasive plants have been found to increase with increasing latitude; however, their water quality niche breadth decreases with increasing latitude, which is due to their long-term adaptations to water eutrophication [27,33]. However, the niche relationships between invasive and native plants along the larger latitudinal gradient are still not well understood.

The alligator weed *Alternanthera philoxeroides*, a type of noxious invasive weed with clonal growth, is native to South America and has extensively invaded the United States, Australia, South Africa, China and other parts of the world [34]. *A. philoxeroides* is an amphibious invader, and in China it has invaded aquatic and terrestrial habitats in more than 20 provinces, causing serious damage to ecological environments and economic development [35]. Previous studies have found that *A. philoxeroides* is more responsive to environmental fluctuations than its native congener *A. sessilis*, and climate warming will promote the climate niche expansion of the terrestrial ecotype of *A. philoxeroides*, intensifying its competitive substitution for native plants at high latitudes [36,37]. In flooded environments, *A. philoxeroides* increases the diameter of its stolon to strengthen its interspecific competitiveness [38]. In addition, with increasing latitudes in China, aquatic *A. philoxeroides* communities have higher β-diversity, while terrestrial *A. philoxeroides* communities have higher similarity [34]. However, the niche characteristics of *A. philoxeroides* and its accompanying species at large spatial scales are unclear.

In this study, we investigated the plant communities invaded by *A. philoxeroides* within the latitudinal range from 21° N to 37° N in mainland China, and we hypothesize that the species niche characteristics of communities invaded by *A. philoxeroides* along a latitudinal gradient have different trends in aquatic and terrestrial habitats. We specifically address the following questions: (1) Do the niche breadth, niche similarity and niche overlap of the *A. philoxeroides* communities in heterogeneous habitats differ? (2) Are the variations in each of the above three indicators different along latitudinal gradients in heterogeneous habitats?

## 2. Materials and Methods

## 2.1. Site Selection

From July to August of 2019–2021, the time of year during which the growth period of plant species is vigorous, we selected sites that were invaded by A. philoxeroides over an area of more than  $100 \text{ m}^2$  to set the sampling plots, and the plots contained low (A. philoxeroides coverage < 40%), moderate (A. philoxeroides coverage was 40%-60%) and heavy (A. *philoxeroides* coverage > 60%) invaded levels. Starting from  $21^{\circ}$  N, a total of 8 latitudinal clusters were set, each 2° apart (the low latitudinal gradient containing Cluster 1: 21° N–23° N and Cluster 2: 23° N–25° N; the middle latitudinal gradient containing Cluster 3: 25° N–27° N, Cluster 4: 27° N–29° N, Cluster 5: 29° N–31° N, and Cluster 6: 31° N-33° N; and the high latitudinal gradient containing Cluster 7: 33° N-35° N and Cluster 8: 35° N-37° N) [34,36,39]. Five terrestrial plots were set along each latitudinal cluster, and five aquatic plots were also set in areas with similar habitat conditions along the same latitudinal cluster [35]. The area of each plot was 10 m  $\times$  10 m, and plots with the same ecotype were set at intervals of more than 10 km [39]. In total, we set 80 sampling plots (40 terrestrial and 40 aquatic; Figure 1), with the types of terrestrial sites mainly comprising roadsides (13 plots), gardens (8 plots), abandoned land (7 plots), farmland (7 plots) and riparian zones (5 plots), while the types of aquatic sites comprised ponds (12 plots), rivers (10 plots), puddles (9 plots), water channels (6 plots) and paddy fields (3 plots) (Supplementary Table S1). For the sampling sites in which there may be a fluid transition between terrestrial and aquatic habitats or in which there may be intermittent changes in habitat type due to climate fluctuations, we combined the morphological plasticity of A. philoxeroides to identify the type of plot in question. The whole study area covered 20 cities within 10 provinces in China and spanned 3 climatic regions, including tropical, subtropical and temperate regions.

## 2.2. Field Survey

For terrestrial plots and some aquatic plots with shallow water levels, we evenly set three 10 m transects in each plot and then evenly set five quadrats with an area of 0.5 m × 0.5 m along each transect for the plant investigation [35,37,40]. For a few aquatic plots with deep water levels, to facilitate the investigation, we chose a blanket patch of *A. philoxeroides* that was close to the bank and set three continuous 10 m transects along the horizontal direction of the aquatic *A. philoxeroides* patches for investigation. We used the survey method of Wu et al. (2016) to record the names, height and coverage of the plant species in every quadrat [39]. We also recorded the individuals (for nonclonal plants), tillers (for graminaceous plants) or numbers of asexual branches (for clonal plants) as the abundance of plant species in each quadrat [35,39]. The longitude, latitude and altitude of every plot were recorded using a handheld GPS receiver (Garmin Inc., Olathe, KS, USA). Photos or collected samples of unknown plants were taken during the field survey, and we then used the 'Chinese Virtual Herbarium' (https://www.cvh.ac.cn, accessed on 10 March 2023) and the online database 'Flora of China' (http://www.iplant.cn/frps, accessed on 10 March 2023) to conduct species identification.

**Figure 1.** Sampling plots of *A. philoxeroides*-invaded communities in China along latitudinal gradients (21° N to 37° N). Plot size:  $10 \times 10$  m; transect size: 10 m; quadrat size:  $0.5 \times 0.5$  m.

## 2.3. Data Calculation

#### 2.3.1. Importance Value

We used the importance value (IV) as a comprehensive indicator to measure the dominance of plants in the *A. philoxeroides*-invaded communities. The IV was calculated as follows [39]:

- 1. IV = (relative abundance + relative height + relative coverage)/3.
- 2. The total IV was the sum of a plant species' IV in 40 terrestrial or 40 aquatic plots.

#### 2.3.2. Niche Characteristics

Each plot in this study was regarded as a comprehensive resource level. Based on the occurrence frequency of plant species in the plots (Table 1), we used the abundance and IV of 25 main plant species (frequency > 9) in the terrestrial plots vs. 24 main plant species (frequency > 4) in the aquatic plots as comprehensive indicators to measure their niche characteristics. The results calculated using this method better reflected the efficiency of the plant species' utilization of environmental resources and could prevent errors caused by individual size differences in each species.

Niche breadth represents the sum of the multiple environmental resources that are used by organisms. Plants with a higher niche breadth can better utilize resources and tend to be generalized species, while plants with a lower niche breadth tend to be specialized species. We calculated niche breadth values using Levins' method as follows [41]:

$$B_{(L)} = 1/(\mathbf{r} \times \sum_{j=1}^{r} P_{ij}^2)$$
(1)

where  $B_{(L)}$  is the species' niche breadth,  $P_{ij}$  is the relative IV of the *i*th species in the *j*th plot and *r* is the total number of sampling plots.

Niche similarity represents the similarity degree of the species' resource utilization, and a lower niche similarity indicates that there are differences in resource utilization between plant species and that they might coexist in the community for a long time. We calculated the niche similarity value using the Schoener index as follows [42]:

$$C_{ik} = 1 - \frac{1}{2} \sum_{j=1}^{r} |P_{ij} - P_{kj}|$$
<sup>(2)</sup>

where  $C_{ik}$  is the niche similarity value between species *i* and *k*, and  $P_{kj}$  is the relative IV of the *k*th species in the *j*th plot.

Niche overlap represents the degree of species with similar niches sharing or competing for common resources when living in the same space; the greater the niche overlap value, the greater the similarity in resource utilization and the more intense the interspecific competition. Niche overlap was calculated as follows [43]:

$$L_{ih} = B_{(L)i} \sum_{j=1}^{r} P_{ij} \times P_{hj}$$
(3)

$$L_{hi} = B_{(L)h} \sum_{j=1}^{r} P_{ij} \times P_{hj}$$

$$\tag{4}$$

where  $L_{ih}$  is the niche overlap value of species *i* overlapping species *h*,  $L_{hi}$  is the niche overlap value of species *h* overlapping species *i*,  $P_{hj}$  is the relative IV of the *h*th species in the *j*th plot,  $B_{(L)i}$  is the niche breadth of species *i* and  $B_{(L)h}$  is the niche breadth of species *h*.

**Table 1.** Niche breadth  $(B_{(L)})$  of plant species with a high frequency in terrestrial and aquatic *A. philoxeroides*-invaded communities.

## 2.4. Statistical Analyses

We conducted an independent sample *t* test (subset for  $\alpha = 0.05$ ) to compare the differences in the plant species' niche characteristics between terrestrial and aquatic communities using SPSS16.0 software (SPSS Inc., Chicago, IL, USA) and conducted a one-way ANOVA and multiple comparisons of least-significant difference (LSD) to examine the variations in niche characteristics along the latitudinal gradient.

## 3. Results

## 3.1. Niche Characteristics at the Level of the Whole Community

## 3.1.1. Niche Breadth

The species niche breadth in the terrestrial communities was 0.099–0.960, and that of the aquatic communities was 0.041–0943. Of the habitat types, the heterogeneous habitats had the largest *A. philoxeroides* niche breadth (terrestrial  $B_{(L)} = 0.960$ , aquatic  $B_{(L)} = 0.943$ ) (Table 1). In the terrestrial communities, the species with higher niche breadth values were *Digitaria sanguinalis*, *Bidens pilosa*, *Setaria viridis* and *Echinochloa crusgalli*, and *Oxalis corniculata* had the lowest niche breadth (Table 1). In the aquatic communities, *Paspalum paspaloides*, *Polygonum hydropiper*, *B. pilosa* and *E. crusgalli* also had higher niche breadth values, and *Microstegium nodosum* had the lowest niche breadth (Table 1). The *t* test showed that there was no significant difference in the niche breadth values of the common species between the terrestrial and the aquatic communities (t = 1.598, p = 0.117).

## 3.1.2. Niche Similarity

A total of 25 plant species in the terrestrial community formed 300 species pairs, and the values of their niche similarity were 0–0.547. Among these values, the niche similarity of two species pairs was more than 0.5 (containing *A. philoxeroides–D. sanguinalis, S. viridis–Humulus scandens*), accounting for 0.67% of the total species pairs. The niche similarity values of 11 species pairs were 0.4–0.5, accounting for 3.67% of the total species pairs. The niche similarity values of 46 species pairs were 0.3–0.4, accounting for 15.33% of the total number of species pairs. The niche similarity of 241 species pairs was less than 0.3, accounting for 80.33% of the total number of species was generally higher than that between each accompanying species (Figure 2a).

There were 276 species pairs formed from 24 plant species in the aquatic communities, with a niche similarity of 0–0.511. The niche similarity of one species pair was more than 0.5 (*C. rotundus–Kyllinga brevifolia*), accounting for 0.36% of the total species pairs. The niche similarity of seven species pairs was 0.4–0.5, accounting for 2.54% of the total species pairs. The niche similarity of 20 species pairs was 0.3–0.4, accounting for 7.25% of the total species pairs. The niche similarity of 248 species pairs was less than 0.3, accounting for 89.85% of the total species pairs (Figure 2b). The *t* test showed that the niche similarity between *A. philoxeroides* and its accompanying species in the terrestrial communities was significantly higher than that between *A. philoxeroides* and its accompanying species in the aquatic communities (t = 5.954, p < 0.001).

**Figure 2.** Niche similarity of plant species with a high frequency in terrestrial (**a**) and aquatic (**b**) *A. philoxeroides*-invaded communities. Arabic numbers are codes of plant species (as shown in Table 1 for terrestrial and aquatic communities, respectively).

## 3.1.3. Niche Overlap

The species niche overlap values of the terrestrial communities were 0–0.026. The niche overlap between *A. philoxeroides* and its accompanying species was 0.022–0.026, which was generally higher than that between each accompanying species. The niche overlap of *A. philoxeroides-P. paspaloides* was the highest. The niche overlap of 49 species pairs was more than 0.01, accounting for 16.33% of the total species pairs. The niche overlap values of 64 species pairs were 0.005–0.01, accounting for 21.33% of the total species pairs. The niche overlap of 187 species pairs was less than 0.005, accounting for 62.33% of the total species pairs.

In the aquatic communities, the species niche overlap values were 0–0.029. The niche overlap values between *A. philoxeroides* and its accompanying species were 0.017–0.029, which were generally higher than those between each accompanying species. The niche overlap values of *A. philoxeroides–Symphyotrichum subulatum* and *A. philoxeroides–M. nodosum* were both the highest. The niche overlap values of 58 species pairs were more than 0.01, accounting for 21.01% of the total species pairs. The niche overlap values of 56 species pairs were 0.005–0.01, accounting for 20.29% of the total species pairs. The niche overlap values of 162 species pairs were less than 0.005, accounting for 58.70% of the total species pairs. The *t* test showed that there was no significant difference in the niche overlap of *A. philoxeroides–*accompanying species between terrestrial and aquatic communities (t = 0.488, p = 0.630).

## 3.2. Latitudinal Trends of Niche Characteristics

## 3.2.1. Variations in Niche Breadth along the Latitudinal Gradient

The niche breadth of *A. philoxeroides* had no obvious fluctuations along the latitude gradient. For the accompanying species in the terrestrial communities, compared to the other species, *Commelina communis*, *B. pilosa* and *Eleusine indica* had greater niche breadths at low latitudes; *D. sanguinalis*, *E. indica*, *E. crusgalli* and *S. viridis* had greater niche breadths at middle latitudes; and *S. viridis* and *H. scandens* had greater niche breadths at high latitudes. Conspicuously, *D. sanguinalis* always had greater niche breadths along the whole latitudinal gradient (Figure 3a). The ANOVA showed that the average niche breadth of the accompanying species significantly decreased with increasing latitude in the terrestrial habitats ( $F_{7,57}$  = 4.364, p = 0.001); in particular, the niche breadth of Cluster 2 at low latitudes was significantly higher than that at middle and high latitudes.

In the aquatic communities, *P. hydropiper* and *E. crusgalli* had greater niche breadths at low latitudes, *P. paspaloides* had an extremely large niche breadth at middle latitudes, and *P. paspaloides*, *E. crusgalli* and *P. hydropiper* had greater niche breadths at high latitudes (Figure 3b). The ANOVA showed that the average niche breadth of the accompanying species in the aquatic community had no significant latitudinal trend ( $F_{7,45} = 1.170$ , p = 0.343).

Figure 3. Variations in niche breadth of the accompanying species along a latitudinal gradient in terrestrial (a) and aquatic (b) *A. philoxeroides*-invaded communities. **Definition of abbreviations:** Aa—*Alopecurus aequalis*; Ac—*Ageratum conyzoides*; As—*Asarum sagittarioides*; Ase—*Alternanthera sessilis*; Bp—*Bidens pilosa*; Bpa—*Broussonetia papyrifera*; Bpl—*Bolboschoenus planicul-mis*; Bs—*Beckmannia syzigachne*; Cc—*Commelina communis*; Cd—*Cynodon dactylon*; Cde—*Ceratophyllum demersum*; Cr—*Cyperus rotundus*; Cv—*Cyperus votundus*; Ds—*Digitaria sanguinalis*; Ea—*Erigeron annuus*; Ec—*Echinochloa crusgalli*; Eca—*Echinochloa caudata*; Ecan—*Erigeron canadensis*; Ecr—*Eichhornia crassipes*; Ei—*Eleusine indica*; Ep—*Eclipta prostrata*; Go—*Galium odoratum*; Gs—*Glycine soja*; Hs—*Humulus scandens*; Ia—*Ipomoea aquatica*; In—*Ipomoea nil*; Lc—*Leptochloa chinensis*; Lm—*Lemna minor*; Mn—*Microstegium no-dosum*; Mv—*Myriophyllum verticillatum*; Oj—*Oenanthe javanica*; Pa—*Phragmites australis*; Pb—*Panicum bisulcatum*; Ph—*Polygonum hydropiper*; Pp—*Paspalum paspaloides*; Ps—*Pistia stratiotes*; Pu—*Phyllanthus urinaria*; Sc—*Sesbania cannabina*; Ss—*Symphyotrichum subulatum*; Sv—*Setaria viridis*; Ts—*Trigastrotheca stricta*; Vp—*Veronica polita*. A and C, A and BC indicate the significant difference, respectively.

The niche similarity between *A. philoxeroides* and its accompanying species was generally higher than that between each accompanying species, and with increasing latitude, the niche similarity showed an overall downward trend. In the terrestrial community, the species pairs of *A. philoxeroides–C. communis, A. philoxeroides–D. sanguinalis, A. philoxeroides–B. pilosa, C. communis–P. paspaloides* and *B. pilosa–E. indica* had higher niche similarity at low latitudes than at other latitudes; *A. philoxeroides–E. indica, A. philoxeroides–D. sanguinalis, A. philoxeroides–S. viridis, E. crusgalli–S. viridis, E. indica–S. viridis* and *H. scandens–S. viridis* had higher niche similarity at middle latitudes; and *A. philoxeroides–H. scandens, A. philoxeroides–Ipomoea nil, H. scandens–E. crusgalli* and *D. sanguinalis–E. crusgalli* had higher niche similarity at high latitudes (Figure 4a). The ANOVA showed that niche similarity between *A. philoxeroides* and its accompanying species significantly decreased with increasing latitude in the terrestrial habitats ( $F_{7,57} = 3.671$ , p = 0.003), especially the niche similarity of Cluster 2 at low latitudes, which was significantly higher than that at middle and high latitudes (Figure 5a).

In aquatic communities, the species pairs of *A. philoxeroides–Pistia stratiotes*, *A. philoxeroides–Eichhornia crassipes*, *A. philoxeroides–P. paspaloides*, *P. stratiotes–Asarum sagittarioides* and *Bolboschoenus planiculmis–Panicum bisulcatum* had higher niche similarity at low latitudes than at the other latitudes; *A. philoxeroides–P. paspaloides*, *A. philoxeroides–I. nil*, *A. philoxeroides–E. caudata*, *A. philoxeroides–Myriophyllum verticillatum* and *P. paspaloides– P. bisulcatum* had higher niche similarity at middle latitudes; and *A. philoxeroides–Phragmites australis*, *A. philoxeroides–S. subulatum*, *P. paspaloides–Oenanthe javanica* and *Ceratophyllum demersum–E. crusgalli* had higher niche similarity at high latitudes (Figure 4b). The ANOVA showed that the niche similarity between *A. philoxeroides* and its accompanying species of each cluster had no significant latitudinal trend in the aquatic habitat (F<sub>7,45</sub> = 0.981, *p* = 0.459) (Figure 5b).

**Figure 5.** Variations in niche similarity between *A. philoxeroides* and the dominant accompanying species of each latitudinal cluster in terrestrial (**a**) and aquatic (**b**) habitats. A and C, A and BC indicate the significant differences at the p < 0.01 level, respectively; while the A and AB, AB and BC, BC and C indicate no significant difference, respectively.

## 3.2.3. Variations in Niche Overlap along the Latitudinal Gradient

The niche overlap values of *A. philoxeroides* and its accompanying species were generally higher than those of the species accompanying *A. philoxeroides*. With increasing latitude, the niche overlap values between plant species in the *A. philoxeroides*-invaded communities showed an overall downward trend (Figure 6). In the terrestrial communities, the species pairs of *A. philoxeroides–D. sanguinalis, A. philoxeroides–B. pilosa, B. pilosa–E. indica* and *Ageratum conyzoides–C. votundus* had higher niche overlap values at low latitudes than at other latitudes; *A. philoxeroides–A. conyzoides, A. philoxeroides–C. communis, A. philoxeroides–C. votundus*, *E. indica–Erigeron canadensis* and *E. crusgalli–Sesbania cannabina* had higher niche overlap values at middle latitudes; and *A. philoxeroides–S. viridis, A. philoxeroides–D. sanguinalis, A. philoxeroides–L. votundus*, *A. philoxeroides–I. nil, A. philoxeroides–H. scandens, A. philoxeroides–E. crusgalli* and *A. philoxeroides–Cynodon dactylon* had higher niche overlap values at high latitudes (Figure 6a). The ANOVA showed that the niche overlap between *A. philoxeroides* and its accompanying species in Cluster 7 at high latitudes was significantly higher than that at low and middle latitudes ( $F_{7,57} = 8.916$ , p < 0.001) (Figure 7a).

In the aquatic communities, *A. philoxeroides–P. stratiotes, A. philoxeroides–E. crassipes, A. philoxeroides–P. paspaloides, P. stratiotes–A. sagittarioides* and *B. planiculmis* had higher niche overlap values at low latitudes than at other latitudes; *A. philoxeroides–P. paspaloides, A. philoxeroides–I. nil, A. philoxeroides–E. caudata, A. philoxeroides–M. verticillatum* and *P. paspaloides–P. bisulcatum* had higher niche overlap at middle latitudes; and *A. philoxeroides–P. australis, A. philoxeroides–S. subulatum, P. paspaloides–O. javanica, C. demersum–E. crusgalli, P. paspaloides–P. hydropiper* and *O. javanica–P. hydropiper* had higher niche overlap at high latitudes (Figure 6b). The ANOVA showed that the niche overlap between

*A. philoxeroides* and its accompanying species of each cluster had no significant latitudinal trend in the aquatic habitats ( $F_{7,45} = 1.042$ , p = 0.419) (Figure 7b).

Figure 6. Niche overlap between the dominant species of each latitudinal cluster in terrestrial (a) and aquatic (b) *A. philoxeroides*-invaded communities. Definition of abbreviations: Aa—Alopecurus aequalis; Ac—Ageratum conyzoides; Ap—Alternanthera philoxeroides; As—Asarum sagittarioides; Ase—Alternanthera sessilis; Bp—Bidens pilosa; Bpa—Broussonetia papyrifera; Bpl—Bolboschoenus planiculmis; Bs—Beckmannia syzigachne; Cc—Commelina communis; Cd—Cynodon dactylon; Cde—Ceratophyllum demersum; Cr—Cyperus rotundus; Cv—Cyperus votundus; Ds—Digitaria sanguinalis; Ea—Erigeron annuus; Ec—Echinochloa crusgalli; Eca—Echinochloa caudata; Ecam—Erigeron canadensis; Ecr—Eichhornia crassipes; Ei—Eleusine indica; Ep—Eclipta prostrata; Go—Galium odoratum; Gs—Glycine soja; Hs—Humulus scandens; Ia—Ipomoea aquatica; In—Ipomoea nil; Lc—Leptochloa chinensis; Lm—Lemna minor; Mn—Microstegium nodosum; Mv—Myriophyllum verticillatum; Oj—Oenanthe javanica; Pa—Phragmites australis; Pb—Panicum bisulcatum; Ph—Polygonum hydropiper; Pp—Paspalum paspaloides; Ps—Pistia stratiotes; Pu—Phyllanthus urinaria; Sc—Sesbania cannabina; Ss—Symphyotrichum subulatum; Sv—Setaria viridis; Ts—Trigastrotheca stricta; Vp—Veronica polita.

## 4. Discussion

## 4.1. Causes of Niche Characteristic Formation in Heterogeneous Habitats

Of the species examined in this study, A. philoxeroides had the greatest niche breadth in both aquatic and terrestrial habitats, reflecting that this invader had a strong ecological adaptation capacity and high resource utilization efficiency, which may be attributed to the cold-tolerant genotype and the growth–defense tradeoff of A. philoxeroides, which has benefited from adapting to harsh habitat conditions and thus occupies a broader niche space [44–46]. This conclusion also supports the niche breadth hypothesis, which states that there is a positive correlation between the size of a species' geographical range and its niche breadth [17], and that plant populations that continuously match habitat conditions will have greater opportunities for distribution expansion [33,47]. However, D. sanguinalis, B. pilosa and S. viridis in the terrestrial habitats and P. paspaloides and P. hydropiper in the aquatic habitats also had greater niche breadths, which might be attributed to their bioproperties. D. sanguinalis and S. viridis had tillering growth and produced massive seeds with strong transmission ability through generative propagation. The tall individuals of B. pilosa and P. hydropiper would imply that they compete for more light resources, while *P. paspaloides* was found to be a perennial species and had both vegetative and generative propagations (Table S2); it could spread rapidly through the rhizomes and stolons. All of these superior functional traits promoted their stable existence at each stage of community succession. Although the niche breadth of most species was positively correlated with their IV in the A. philoxeroides community, some dominant accompanying species, such as S. viridis and C. communis, were incidentally present, indicating that IV was not the unique factor determining niche breadth, and niche breadth might also be determined by the interactive effect of species distribution frequency and habitat heterogeneity [48].

In our study, niche similarity in the terrestrial communities was generally higher than that in the aquatic communities, which might be due to the higher species diversity of the terrestrial communities [37]. Neutral theory states that species similarity rather than species difference contributes to high community diversity; thus, continuous biointeractions among multiple species in terrestrial *A. philoxeroides* communities promote coexistence groups with high niche similarity [49]. In addition, Wu et al. (2022) found that *A. philoxeroides* invasions caused higher community homogenization in terrestrial habitats than in aquatic habitats, and functional groups of Gramineae and Compositae that have strong invasion resistance widely exist in the community [34], which causes the plant species in terrestrial habitats to have closer geographical affinity and facilitates their convergent evolution. Moreover, environmental filtering caused by strong disturbances (e.g., human disturbances and insect feeding) in terrestrial habitats have led to the repeated colonization of plant species in the same species pool, which have caused similar species to show obvious aggregation and thus facilitated the coexistence of species with high niche similarity [19]. However, the

structure of aquatic communities is relatively simple and is more sensitive to environmental changes; thus, aquatic plant species might require a smaller niche similarity to maintain survival [50].

Species niche overlap in terrestrial and aquatic habitats was low, indicating that plant species in the A. philoxeroides-invaded communities tended to reduce their niche overlap to coexist in large-scale spaces [18]. However, the niche overlap between A. philoxeroides and its accompanying species was higher than that between each accompanying species, indicating that A. philoxeroides, as an invader, had stronger competitiveness; it competed for resources with most plant species and even with narrow-niche species. Interestingly, the niche similarity and niche overlap of species pairs such as A. philoxeroides-D. sanguinalis and A. philoxeroides–P. paspaloides were all high, indicating that they had highly similar living habits and resource requirements and that more intense interspecific competition might thus occur with community succession. Previous studies have found that plant invasions cause a decline in niche overlap among native plants and thus enhance the competition between invasive and native plants [51]. Similarly, we also found that the accompanying species with large niche breadth did not form species pairs with higher niche overlap in the A. *philoxeroides* community, indicating that the resource utilization capacity of the accompanying species was weaker than that of A. philoxeroides at large spatial scales and that they might choose to reduce interspecific competition and/or improve mutual assistance for resisting invasion [29].

## 4.2. Causes of Niche Breadth Variations along the Latitudinal Gradient in Heterogeneous Habitats

Niche theory predicts that with changes in the environmental gradient, the difference in species specificity during the process of adaptive evolution will lead to changes in community structures [16]. Habitat heterogeneity can improve the phenotypic plasticity of plant species, while latitudinal gradients facilitate the continuous evolution of species ecological strategies [45]. In our study, the niche breadths of *A. philoxeroides* in both terrestrial and aquatic habitats were high, and no obvious latitudinal trend was observed, suggesting that the niche breadth of this species might be determined by both adaptive variation and phenotypic plasticity; thus, a larger niche breadth could benefit *A. philoxeroides* in resisting environmental fluctuations [26,45]. Previous studies have found that the phenotypic plasticity of *A. philoxeroides* increased with increasing latitude, reflecting its strong adaptations to changes in temperature, precipitation and herbivory along a latitudinal gradient, thus leading to the large niche breadth of *A. philoxeroides* in each latitudinal cluster [52–54]. This scenario may also have occurred because *A. philoxeroides*, as a pioneer species, has strong environmental tolerance; it can share similar habitat conditions at different latitudes and spread to higher latitudinal regions under climate change [36,55,56].

Temperature is the crucial factor affecting plant growth, and the distributions of plant species in terrestrial ecosystems are more vulnerable to thermal variations than to other variations [10]. Low-latitude regions have sufficient heat and exacerbate the competition between each accompanying species, while the cold climate of high latitudes might mitigate interspecific competition. However, invasive plants can continuously establish populations in new habitats at high latitudes and reduce the niche breadth of the accompanying plants by disturbing their competition and coexistence patterns [47]. In our study, species with larger niche breadths, such as H. scandens, which had both vegetative and generative propagations, and *S. viridis*, which had tall individuals (Table S2), also appeared in high-latitude terrestrial communities, which may be due to the continuous evolution of native species to increase their competitive tolerance and thus reduce their sensitivity to bioinvasions [57]. As the community size increased, the proportion of species with extreme specialization also increased, and the difference in their niche breadths was further amplified. Compared to terrestrial communities, aquatic communities that have simpler structures and lower species diversity are more vulnerable to plant invasions [10,32]. A. philoxeroides has extensively invaded various aquatic habitats, and tends to form monodominant populations, which results in the niche breadths of the aquatic accompanying species having no obvious latitudinal trend.

# 4.3. Causes of Niche Similarity and Overlap Variations along the Latitudinal Gradient in Heterogeneous Habitats

In the terrestrial community, the niche similarity between A. philoxeroides and its accompanying species at low latitudes was relatively high, indicating that the accompanying species tended to possess climate adaptability similar to that of A. philoxeroides, and thermal stability promoted the coevolution of plant species in the low-latitude regions. Each accompanying species also had high niche similarity for preferably adapting to the coexistence environment, which was conducive to the formation of higher species diversity at low latitudes [58,59], and environmental filtering led to obvious aggregation in these regions [19]. A. philoxeroides has high phenotypic plasticity and compensatory growth capacity at high latitudes [39], but the cold climate at high latitudes limits the growth of native species. Only a few species with strong environmental tolerance can share resources with A. philoxeroides and thus have higher niche similarity, and most of the remaining species pairs have low niche similarity [45]. The niche similarity between A. philoxeroides and its accompanying species in the aquatic habitats had no obvious latitudinal trend because the water bodies buffered temperature fluctuations caused by latitude changes; thus, they were more stable than terrestrial habitats [60]. However, A. philoxeroides invasion was more significant in aquatic habitats, and the accompanying species thus suffered from stronger competitive exclusion [35].

A. philoxeroides had high niche overlap with its accompanying species in the heterogeneous habitats, indicating that it had a higher competitive advantage than native species. In terrestrial habitats, the niche overlap between A. philoxeroides and its accompanying species significantly increased with increasing latitude, particularly in latitudinal Cluster 7, which may imply that A. philoxeroides strengthened competition with its accompanying species by increasing the niche overlap under increased environmental stress; in turn, the resource utilization of the accompanying species decreased, reducing their adaptability to harsh environments and thus inhibiting native plant establishment at high latitudes [58,59]. However, the niche overlap between A. philoxeroides and its accompanying species in aquatic habitats had no obvious latitudinal trend, possibly due to aquatic plant species experiencing severe A. philoxeroides invasion at all latitudinal clusters [61]. In this study, niche overlap between A. philoxeroides and P. stratiotes and E. crassipes was higher at low latitudes; these are all globally invasive weeds with vegetative propagation, indicating that they may have similar survival needs for dissolved oxygen, light and water flow and may also provide interspecific mutual assistance [62,63]. Attention must be paid to this phenomenon of collaborative aquatic plant invasions at low latitudes because with rapid global warming, the superior hydrothermal conditions at low latitudes will accelerate the niche expansion and coevolution of aquatic invasive plants originating from tropical America [61,64]. In addition, there were over 10 forms and varieties of A. philoxeroides in the natural ecosystems, which made the taxonomy of A. philoxeroides one of the most complicated taxa among Alternanthera [65,66]; thus, it is necessary to fully assess the influence of taxonomic differences of A. philoxeroides on its niche characteristics in future studies.

## 5. Conclusions

We found that, of the studied species, *A. philoxeroides* had the greatest niche breadth in both aquatic and terrestrial habitats and that the niche similarity and overlap between *A. philoxeroides* and its accompanying species were all high. The niche similarity of *A. philoxeroides* in the terrestrial communities was significantly higher than that in the aquatic communities, while the niche similarity and overlap between each accompanying species were low. The niche breadth of *A. philoxeroides* had no obvious latitudinal trend, which was attributed to its strong environmental tolerance. In the terrestrial communities, the niche similarity of *A. philoxeroides* and the niche breadth of its accompanying species all significantly decreased with increasing latitude, while the niche overlap between *A. philoxeroides* and its accompanying species significantly increased with increasing latitude. However, the niche characteristics in the aquatic communities had no obvious latitudinal trend. These findings indicate that habitat heterogeneity significantly affects the niche characteristics of the *A. philoxeroides* community and that *A. philoxeroides* invasion might weaken the interspecific competition of its accompanying species. At low latitudes, environmental filtering resulted in species with similar niches in the *A. philoxeroides* communities showing obvious aggregation, and the invasive and native species tended to evolve similar environmental capacities. At high latitudes, the restrictions of the cold climate led to an increase in niche overlap between *A. philoxeroides* and its accompanying species.
