Incorporating the Soil Gas Gradient Method and Functional Genes to Assess the Natural Source Zone Depletion at a Petroleum-Hydrocarbon-Contaminated Site of a Purification Plant in Northwest China

Zhuo Ning 1,2,†, Yizhi Sheng 3,†, Caijuan Guo 1,2, Shuaiwei Wang 1,2, Shuai Yang 4 and Min Zhang 1,2,*

Abstract: An increasing number of studies have demonstrated that natural source zone depletion (NSZD) in the vadose zone accounts for the majority (90%–99%) of the natural attenuation of light non-aqueous phase liquid (LNAPL). Until now, 0.05 to 12 kg/a.m² NSZD rates at tens of petroleum LNAPL source zones have been determined in the middle or late evolution stage of LNAPL release, in which limited volatile organic compounds (VOCs) and methane (CH₄) were detected. NSZD rates are normally estimated by the gradient method, yet the associated functional microbial activity remains poorly investigated. Herein, the NSZD at an LNAPL-releasing site was studied using both soil gas gradient methods quantifying the O₂, CO₂, CH₄, and VOCs concentrations and molecular biology methods quantifying the abundance of the pmoA and mcrA genes. The results showed that the methanogenesis rates were around 4 to 40 kg/a.m². The values were greater than the rates calculated by the sum of CH₄ escaping (0.3–1.2 kg/a.m²) and O₂ consuming (3–13 kg/a.m²) or CO₂ generating rates (2–4 kg/a.m²), suggesting that the generated CH₄ was oxidized but not thoroughly to CO₂. The functional gene quantification also supported the indication of this process. Therefore, the NSZD rates at the site roughly equalled the methanogenesis rates (4–40 kg/a.m²), which were greater than those of the previously studied sites with a 90th percentile value of 4 kg/a.m². The study extended the current knowledge of the NSZD and has significant implications for LNAPL remediation management.

Keywords: natural source zone depletion (NSZD); petroleum hydrocarbon contaminated site; gradient method; functional gene

1. Introduction

Natural source zone depletion (NSZD) is the natural loss of light non-aqueous phase liquid (LNAPL) through collective, naturally occurring processes of volatilization, dissolution, and biodegradation [1–3]. A growing number of studies have demonstrated that NSZD occurs at petroleum-hydrocarbon-contaminated sites at depletion rates ranging from thousands to tens of thousands of liters per hectare per year. Approximately 90% to 99% of the natural attenuation of petroleum hydrocarbons occurs in the vadose zone, the area extending from the surface to the regional groundwater table [4,5]. Across the petroleum-hydrocarbon-contaminated aquifer to the vadose zone, three zones, i.e., the
methane generation zone, methane oxidation zone, and aerobic transport zone are defined by the one-dimensional conceptual model in terms of their key roles in NSZD [6]. Methanogenesis occurs in the saturated aquifer and deep vadose zone (e.g., capillary zone), where the biodegradation of LNAPL compounds is accomplished by a syntrophy between fermenters and methanogens to produce methane (CH$_4$) and carbon dioxide (CO$_2$). Non-syntrophic methanogenic hydrocarbon degradation by an archaeal species has also been found [7]. Through ebullition and diffusion, the generated gases migrate toward the surface. In the vadose zone, aerobic bacteria convert a proportion of CH$_4$ into CO$_2$, which diffuses upward to the surface of the ground.

It is currently possible to determine the NSZD rate using several methods, including gradients, carbon traps, dynamic closed chambers, biogenic heat, and the recently proposed compositional change method for LNAPL, of which the first four methods are the most commonly used [8,9]. For each of the four methods, more than ten sites have been studied [9]. The gradient method is the earliest and most well-studied, which was systematically proposed by Johnson et al. [10]. With the help of measurements of the changes in soil gas concentrations and respective stoichiometric relationships, NSZD rates can be readily estimated. The soil-gas constituent concentration gradients are obtained by assessing the changes in the vertical distribution of soil gas constituents (O$_2$, CO$_2$, CH$_4$, and vapor-phase petroleum hydrocarbon) in the vadose zone above the LNAPL source. Combined with the estimated or field-measured soil gas effective diffusion coefficient, the gaseous mass flux is calculated using Fick’s first law of diffusion. Stoichiometric conversion of the biodegradation product mass flux then allows an estimate of the rate of LNAPL mass depletion [8]. The gradient method gives instantaneous measurement and facilitates the identification of distinct physicochemical pathways in NSZD [11]. Owing to its advantages, this method has been universally applied to estimate NSZD under various conditions [5]. The method was first applied in an aged oil field [8,12]. Gradient methods were then used to estimate NSZD rates in various LNAPL-contaminated sites, including crude oil, diesel, jet fuel, and gas condensate, etc. [4,13–17].

A majority of the studies were conducted in closed sites at mid- or late-stages in LNAPL release [14,18], during which fewer volatile petroleum hydrocarbons and CH$_4$ were detected in the vadose zone. As such, volatile petroleum hydrocarbons and CH$_4$ were always excluded or omitted when calculating NSZD rates [19]—whereas in the early evolutionary stage of LNAPL-releasing sites, CH$_4$ and VOCs should be taken into account [4]. Moreover, microbial activities during NSZD have rarely been investigated.

In the study, therefore, NSZD at a LNAPL-releasing site of a purification plant in Northwest China was assessed by the gradient method coupled with the quantification of the core genes encoding the methanogenesis and methane oxidation processes. This study extended for the first time the current knowledge of NSZD assessment in China, which is broadly applicable to thousands of similar petroleum-hydrocarbon-contaminated sites [20].

2. Materials and Methods

2.1. Site Description

The study site is located near the gas condensate storage tanks at a purification plant in Northwest China. The depth of the water table at the site ranges from 3.2 to 4.7m below the ground surface. The vadose zone and saturated zone are primarily composed of fine sands. The groundwater flow direction is generally from north to south. Due to the gas condensate released from the storage tanks and the impact of groundwater flow, the contaminants spread nearly all over the site (Figure 1a). LNAPL was mainly present in the zone of water table fluctuation (Figure 1b). Contaminants at the site were largely occupied by the light-end petroleum hydrocarbons such as benzenes and other smaller molecule volatile petroleum hydrocarbons ($C_6$–$C_9$).
2.2. Sampling, Gas Measurement, and Functional Gene Determination

The most likely contamination source zone to the north of the in-service storage tanks was chosen to assess the rate of natural source zone depletion. Regarding the complex pipeline underground and the presence of flammable and explosive hydrocarbons, it was a forbidden area for traditional invasive drilling and long-term retention of monitoring wells according to the strict rules of the plant. To gain the NSZD rate and data on the different physicochemical pathways of NSZD, a minimally invasive measurement was carried out in the study area. The area was divided into 3 one-meter square blocks (Figure 1a). All blocks were treated as replicates. The concentrations of soil gases and functional genes were measured in each block. Meanwhile, the non-contaminated area was chosen as the background.

(1) Soil gas concentration measurement

Using a 2-cm-diameter, 1.0-m-long copper drill rod hammered with a copper hammer, boreholes with different depths were drilled. First, a 10-cm-deep hole was drilled. The concentrations of VOCs, CO₂, O₂, H₂, and CH₄ were immediately measured in the drilled hole using a portable multi-parameter gas detector (MultiRAE 6208, USA). Afterward, in the same way, the hole was deepened to 20 cm and the gas concentrations were measured. The same procedure was applied to a depth of 90 cm. Triplicate measurements were conducted in each block.

Due to the fact that the gas measured in the borehole was a mixture of gas extracted from different soil depths, the measured concentrations in each layer might not fully represent their real concentrations. In the current study, to obtain the real concentration in each layer, we proposed a procedure to estimate the real gas concentrations in a certain depth layer.

The assumptions of the measurement were i) the soil column is homogeneous within 90 cm, i.e., the gas permeabilities are uniform; ii) at the same depth, the gas concentrations are the same anywhere; iii) during the course of gas extraction and measurement, the gas is equally extracted from different depths, i.e., soil gases from different depths have the same contribution; iv) when the measured gas concentration values are stabilized, the stabilized values represent the soil gas concentrations.

Then, the amount of a certain gas in the layer between \((x - d)\) and \(x\) depths (Figure 2) can be expressed as
\begin{equation}
M(x - d, x) = \int_{x-d}^{x} C(x) \, dx
\end{equation}

where \( x \) is the depth below the ground surface, m;
\( C(x) \) is the actual gas concentration at \( x \) depth, g/m\(^3\);
\( M(x - d, x) \) is the amount of the gas in the layer between \( x - d \) and \( x \) depths, g/m\(^2\).

Assuming the measured concentration in the \( x \)-depth hole is \( C_m(x) \), the amount of the gas in the hole can be expressed as

\begin{equation}
M(0, x) = C_m(x) \cdot x
\end{equation}

The amount of the gas in the \( x \)-depth hole can be deemed as the amount of the gas in the \( x - d \) depth hole plus the amount of the gas in the layer between the \( x - d \) and \( x \) depths, and can therefore be expressed as

\begin{equation}
M(0, x) = C_m(x - d) \cdot (x - d) + M(x - d, x)
\end{equation}

\begin{equation}
= C_m(x - d) \cdot (x - d) + \int_{x-d}^{x} C(x) \, dx
\end{equation}

Therefore,

\begin{equation}
C_m(x) \cdot x = C_m(x - d) \cdot (x - d) + \int_{x-d}^{x} C(x) \, dx
\end{equation}

For assessing NSZD in practice, when \( d \) is small enough, between \( x - d \) and \( x \) depths, \( C_o(x) \) can be deemed as a constant value. Then, Equation (4) can be transformed as

\begin{equation}
C_m(x) \cdot x = C_m(x - d) \cdot (x - d) + C(x) \cdot d
\end{equation}

\( C_o(x) \) and \( C_o(x - d) \) in Equation (5) are easily measured. Then, the actual gas concentration at \( x \) depth can be calculated as

\begin{equation}
C(x) = \frac{C_m(x) \cdot x - C_m(x - d) \cdot (x - d)}{d}
\end{equation}

In the present study, \( d \) was set as 0.1 m.

Figure 2. Schematic plot of the soil gas measurement borehole.
(2) Functional gene determination

To verify the crucial biochemical processes upon NSZD, e.g., methanogenesis and methane oxidation, the corresponding functional genes methyl coenzyme M reductase gene \((mcrA)\) and methane monooxygenase gene \((pmoA)\) were quantified. The detailed procedure was as follows: At each depth of the gas concentration measurement, an approximately 50 g soil sample was collected using the Luoyang shovel and sealed in a sterile bag. Then, the soil samples were stored in an incubator filled with dry ice and transported to the laboratory for DNA extraction. The DNA was extracted from 0.8 g soil of each sample using a FastDNA kit (Q-BIO gene Corp. Irvine, CA) [21]. Then, the \(mcrA\) and \(pmoA\) gene abundance was quantified using a fluorescence quantitative PCR instrument (ABI Q5, USA). The PCR primers and detailed experimental procedures are available in the relevant references [22,23].

2.3. Assessment of the Natural Source Zone Depletion

After the \(C(x)\) values of \(O_2\), \(CH_4\), and VOCs were gained, the NSZD rate could be calculated according to Equation [19]

\[
R = -D_{HC} \frac{\partial C_{HC}(x)}{\partial x} - S_{CH_4} \cdot D_{CH_4} \frac{\partial C_{CH_4}(x)}{\partial x} + S_{O_2} \cdot D_{O_2} \frac{\partial C_{O_2}(x)}{\partial x}
\]

where \(\frac{\partial C_{HC}(x)}{\partial x}\), \(\frac{\partial C_{CH_4}(x)}{\partial x}\), and \(\frac{\partial C_{O_2}(x)}{\partial x}\) represent the vertical concentration gradients of hydrocarbon, methane, and oxygen, respectively, at depth \(x\) of the horizontal plane in \((g/m^3)/m\); 

\(S_{CH_4}\) is the stoichiometric coefficient for methanogenesis, and the value is 1.1 g-HC/g-CH\(_4\);

\(S_{O_2}\) is the stoichiometric coefficient for aerobic biodegradation, ranging from approximately 0.25 to 0.29 g hydrocarbon/g \(O_2\) consumed, depending on the relative contributions of direct hydrocarbon aerobic oxidation (0.29 kg hydrocarbon/mg \(O_2\)) and indirect hydrocarbon oxidation (0.25 mg hydrocarbon/mg \(O_2\)) assuming that methane production occurs first in the anaerobic source zone and then methane is subsequently biodegraded aerobically as it diffuses upward;

\(D_{HC}\), \(D_{CH_4}\), and \(D_{O_2}\) represent the effective vapor phase diffusion coefficients for hydrocarbon, methane, and oxygen, respectively, at depth \(x\) of the horizontal plane in \(m^2/s\).

Effective diffusion coefficients were estimated by the most widely used Penman model [24].

\[
D = 0.66 \epsilon \cdot D_0
\]

where \(D\) is the gas diffusion coefficient in soil \((m^2/s)\); 

\(D_0\) is the gas diffusion coefficient in free air \((m^2/s)\); 

\(\epsilon\) is the soil air-filled porosity.

According to Equation (8), the effective vapor phase diffusion coefficients for hydrocarbon (represented by benzene), \(CH_4\), \(O_2\), and \(CO_2\) were calculated to be \(1.27 \times 10^{-4} \ m^2/s\), \(3.08 \times 10^{-5} \ m^2/s\), \(2.47 \times 10^{-5} \ m^2/s\), and \(2.16 \times 10^{-5} \ m^2/s\) respectively. In the estimation, the air-filled porosity was measured to be 0.2 and the gas diffusion coefficients in free air were gained from the work of Massman [25].

In this study, the \(CO_2\) and \(CH_4\) gradients were also used to assess the \(CO_2\) production rate and methanogenesis rate, respectively.
3. Results and Discussion

3.1. Soil Gas Profiles

Based on the minimally invasive measurement of soil gas concentrations, the actual soil gas concentrations in the study area were calculated using Equation (6), and they are shown in Figure 3. It can be observed that the O₂ concentrations rapidly decreased with depth above 60 cm in all blocks, while the VOCs, CO₂, and CH₄ concentrations increased. Below 60 cm depth, the VOCs and O₂ concentrations did not vary with depth and exhibited some fluctuation, while the CO₂ and CH₄ concentrations continued to increase with depth in blocks A and B, and were greater than the upper limits of detection in block C.

![Figure 3](image)

Figure 3. Vertical profile of soil gas O₂, CO₂, CH₄, and VOCs calculated in the study area. Some missed data points at 70~90cm indicated that the concentrations were greater than the upper limits of detection. (a–c) Plots represent the A, B, and C blocks in the contamination source area, respectively.

Although the VOCs were detected and basically increased with depth in all blocks, the concentrations of VOCs are about 2 to 4 orders lower than CO₂ and CH₄. The trend of CO₂ concentration variations and O₂ displayed a significant negative correlation (r = −0.967, p < 0.001). The depth-dependent variations in CH₄ concentration were nonlinear and had different patterns. Above the 50cm, 40cm, and 30cm for blocks A, B, and C, the CH₄ concentration was less than 1% with fewer variations, while below these depths, the CH₄ concentration was greater than 1% and almost linearly increased with depth. The lower CH₄ concentration in the upper layers (<50 cm, 40 cm, and 30 cm for blocks A, B, and C) indicated that there might be less methanogenesis and more methane oxidation, and the O₂ concentration gradients were mainly formed by diffusion.

3.2. Soil Gas Gradients

To calculate the NSZD rate, only the O₂ concentrations in diffusion-dominated areas were taken into consideration. As methane oxidation also generates CO₂, the CO₂ diffusion-dominant areas were the same as for O₂. It was hard to distinguish the CH₄ and VOCs diffusion-dominated areas because CH₄ and VOCs might be oxidized in the space coexisting with O₂. If the oxidation rates were constant at different depths, the concentration gradients would be only caused by diffusion. Upon this assumption, to estimate the rates of VOCs volatilization, the concentrations at the same depths as O₂ diffusion-dominated depths were taken into account; and to estimate the rates of CH₄ generation in the source zone, the concentrations in the soil below the mutational depths (>50 cm, 40 cm, and 30 cm for blocks A, B, and C) were taken into consideration. Herein, the linear curves were fitted with the gas profile data. The fitted depths, calculated gradient, and adj. R² are listed in Table 1.
As shown by the adj. R² values in Table 1, the concentrations of O₂, CO₂, and CH₄ were well fitted, whereas the concentrations of VOCs were not.

3.3. Estimating the NSZD Rates

In agreement with the prior assumption, in the O₂ diffusion-dominated area, all soil gas concentrations only varied by diffusion, and the NSZD rate in each block could be calculated according to Equation (7). The amounts of O₂ consumed hydrocarbons in blocks A, B, and C and the background were calculated to be 3.9 ± 0.4 kg/a.m², 3.5 ± 0.7 kg/a.m², 12.3 ± 0.4 kg/a.m² and 0.1 ± 0.0 kg/a.m², respectively. The amounts of CH₄ escaping to the air corresponding to biodegraded hydrocarbons in blocks A, B, and C and the background were calculated to be 0.9 ± 0.3 kg/a.m², 0.4 ± 0.2 kg/a.m², 0.3 ± 0.0 kg/a.m², and 0.0 kg/a.m², respectively. The calculated VOCs volatilization rates were less than 0.001 kg/a.m² in all areas. Therefore, the total NSZD rates were 4.7 ± 0.7 kg/a.m², 3.4 ± 0.9 kg/a.m², and 12.5 ± 0.4 kg/a.m² in accordance with the O₂ estimation.

In addition to the use of O₂ consumption to estimate the NSZD, the product of hydrocarbon biodegradation, CO₂, was also used to estimate the NSZD. The CO₂ generation corresponding to NSZD fluxes was calculated to be 3.3 ± 0.4 kg/a.m², 2.8 ± 0.5 kg/a.m², 3.4 ± 0.4 kg/a.m², and 0.1 ± 0.0 kg/a.m² in blocks A, B, and C and the background, respectively. Accordingly, the total NSZD rates were 4.1 ± 0.7 kg/a.m², 3.1 ± 0.7 kg/a.m², and 3.7 ± 0.4 kg/a.m² in accordance with the CO₂ estimation.

Based on the CH₄ concentration gradients in the deeper soils (>50 cm, 40 cm, and 30 cm for blocks A, B, and C), the methanogenesis-caused NSZD rates were calculated to be 6.7 ± 2.1 kg/a.m², 9.3 ± 2.4 kg/a.m², and 41.7 ± 1.7 kg/a.m² in the A, B, and C blocks, respectively.

3.4. Functional Genes Evidence

The mcrA gene, encoding the methyl coenzyme M reductase (MCR) complex, remained at a low level in the upper layer until depths deeper than 60 cm, where it remained steady (Figure 4). This trend was the opposite of the depth-dependent oxygen variation. The correlation analysis results showed that mcrA gene concentrations had a significantly negative correlation with O₂ concentrations (r = -0.740, p < 0.001) and a significantly positive correlation with CH₄ concentrations (r = -0.686, p < 0.001), but they were not significantly correlated with VOCs (r = 0.133, p = 0.518).

The concentration of the \textit{pmoA} gene, encoding methane monooxygenase, did not vary as dramatically as the \textit{mcrA} gene (Figure 4). The correlation analysis results showed that the \textit{pmoA} gene had a significantly negative correlation with O\textsubscript{2} \((r = -0.526, p = 0.005)\) and a positive correlation with CH\textsubscript{4} \((r = 0.669, p < 0.001)\). As Figure 5 illustrates, CH\textsubscript{4} and the \textit{pmoA} gene were not linearly correlated. The relationships can be divided into three circumstances: (I) low CH\textsubscript{4} and low-to-middle \textit{pmoA}, corresponding to the samples collected from the surface or near the surface; (II) middle CH\textsubscript{4} and middle \textit{pmoA}, corresponding to the samples collected from the intermediate depth (about 30–80 cm); and (III) high CH\textsubscript{4} and high \textit{pmoA}, corresponding to the samples collected from the deep depth (greater than 60 cm). There was no significant difference between \textit{pmoA} concentrations in group I and group II \((p < 0.05)\), indicating that the CH\textsubscript{4} oxidation rates in these areas were basically invariant, while the \textit{pmoA} concentrations in group III were significantly higher.
4. Discussion

4.1. Biogeochemical Process Process in NSZD

All A-C soil gas profiles displayed more apparent O$_2$ usage and CO$_2$ production in the deeper subsurface. The concentrations of VOCs were about 2 to 4 orders lower than CO$_2$ and CH$_4$, which suggested that nonmethane hydrocarbon contaminants were scarcely depleted through volatilization, but were rather potentially biodegraded by functional microorganisms in the source zone, consistent with previous studies [4,13–17,19]. For the background (uncontaminated) samples, no VOCs and CH$_4$ were generated. The calculated O$_2$ usage and CO$_2$ generation due to hydrocarbon depletion fluxes were both around 0.1 kg/a.m$^2$, which may merely reflect the soil respiration rates [4] and only accounted for 1%~4% of the values in the contaminated samples (i.e., A, B, and C blocks). Taken together, natural depletion was in progress in the source zone.

Below the 50cm, 40cm, and 30cm depths for blocks A, B, and C, the CH$_4$ concentrations were greater than 1% and almost linearly increased with depth. This result was not consistent with most of the sites, where CH$_4$ was always undetected in the vadose zone [4,17,19]. The high concentrations of CH$_4$ may have been caused by the continuous leaking of hydrocarbons in the in-service storage tanks, which supplied enough substrate for methanogenesis [4]. In anaerobic environments contaminated by LNAPLs, fermenters would biodegrade hydrocarbons and form dissolved hydrogen and/or acetate, which would be further utilized by methanogens as a substrate to form methane [26,27]. The lower CH$_4$ concentrations in the upper layers (<50 cm, 40 cm, and 30 cm for block A, B, and C) indicated that there might be less methanogenesis and more methane oxidation, and the O$_2$ concentration gradients were mainly formed by diffusion. In the deeper layers, O$_2$ may also be consumed by methane oxidation. Taken together, the soil gas profiles in the study area were consistent with the NSZD model showing the presence of both aerobic and anaerobic biodegradation in the source zone of the site.

The CO$_2$ estimated NSZD rates (2.4~4.8 kg/a.m$^2$) were slightly lower than the O$_2$ estimated values (2.5~12.9 kg/a.m$^2$). CO$_2$ is the ultimate product of hydrocarbon biodegradation; therefore, some intermediate products are excluded when estimating NSZD using CO$_2$. While O$_2$ is used, some hydrocarbons may not be thoroughly biodegraded to CO$_2$ but are included in the NSZD calculation. This may result in lower estimated values of CO$_2$. According to the NSZD concept model, as for O$_2$-consuming processes in the vadose zone, only CH$_4$ oxidation is taken into consideration. Therefore, it is essential to evaluate the methanogenesis fluxes.

The calculated NSZD rates caused by methanogenesis (4~40 kg/a.m$^2$) were greater than the NSZD rates estimated by both O$_2$ and CO$_2$ gradients. One plausible reason is that the generated CH$_4$ was not thoroughly oxidized to CO$_2$. The stoichiometric relationships between O$_2$ consuming (or CO$_2$ generating) and hydrocarbon biodegrading processes in Equation (7) are based on the reaction that CH$_4$ is thoroughly oxidized to CO$_2$. However, in the natural environment, there are several steps to convert CH$_4$ to CO$_2$. CH$_4$ may firstly be oxidized to methanol, and then formaldehyde, etc. If CH$_4$ was not thoroughly oxidized to CO$_2$, although it was oxidized, the O$_2$ consumption would be low, and there would be less—or even no—CO$_2$ generated. This speculation is consistent with the calculated results: CH$_4$ generating rates > (O$_2$ consuming + CH$_4$ escaping) rates > (CO$_2$ generating + CH$_4$ escaping) rates. Although the methanogenesis fluxes were different in different blocks, the CO$_2$ generating flux was almost the same. Methanogenesis may not be the rate-limiting process for the mineralization of hydrocarbons due to a suite of environmental constraints [28,29], although methanogenesis has been deemed to be the rate-limiting process for NSZD [11].

Another possible reason is the overestimated gradients of CH$_4$. In the estimated area, besides diffusion, there may be the presence of CH$_4$ oxidation and/or methanogenesis, which would vary the diffusion gradients. If the net consumed CH$_4$ (the oxidized CH$_4$ minus generated CH$_4$) in the upper soils was greater than in the deeper soils, the gradient...
would be overestimated and vice versa. However, it was hard to calculate the net consumed CH₄ dependent upon the monitored soil gas concentrations. Functional gene quantification may help to differentiate the CH₄ oxidation or methanogenesis processes. The significantly negative correlation between the mcrA gene and oxygen concentrations was consistent with the consensus that anaerobic conditions are necessary for methanogenesis [30]. Although the mcrA gene was expected to be positively correlated with CH₄, it was not significantly correlated with VOCs. Considering the low VOCs concentrations, therefore, most of the methane might not be generated by the biodegradation of VOCs in the vadose zone but by the biodegradation of petroleum hydrocarbons in the LNAPLs zone, consistent with the hypothesis of the calculation model (Equation (7)). It should be noted that MCR complexes (mcrABG subunits) can also serve as a core gene for anaerobic methane oxidation, but only in a few methanogens [31].

As the pmoA product is an O₂-dependent enzyme [32], the negative correlation with O₂ suggested that O₂ was not a limiting factor for methane oxidation at the study depth. The positive correlation with CH₄ suggested that the amount of CH₄ provided methane oxidation activity. The pmoA concentrations in group III were higher, indicating that the CH₄ oxidation rates in the deeper soil layers were greater than those in the upper layers. The results also indicated that the CH₄ oxidation zone occurred in the deeper soils, and the CH₄ concentration gradients in the shallow depth (<60 cm) were primarily formed by diffusion, which conformed to the application condition of the NSZD assessment model. Furthermore, pmoA abundance was several orders of magnitude higher than that of the mcrA gene. This finding suggested that methane at the study depth might be mostly consumed rather than generated by functional microorganisms, and the net consumed CH₄ in upper soils might be less than those in the lower soils. This would cause an under-estimation of the gradients of CH₄. Therefore, the second possible reason for the greater methanogenesis rates is invalid, and the estimated rates of methanogenesis above were conservative. Therefore, methanogenesis was the rate-limiting process for NSZD at the study site, and the actual NSZD rates roughly equaled the methanogenesis rates, which is consistent with the previous study [11].

4.2. Environmental Implications

The calculated NSZD rates differed using different gas gradients. The different rates pointed to the different physicochemical pathways. In this study, the methanogenesis rates might equal the total NSZD rates. The NSZD rate values of 4~40 kg/a.m2 are greater than 90% of the 40 LNAPL sites with a 90th percentile value of 4 kg/a.m² [9]. As previously investigated, the greatest NSZD rate was about 12 kg/a.m², which was gained from accidental releases of denatured fuel-grade ethanol-affected sites [33]. The higher NSZD rates in our site might be caused by ongoing leaking from the storage tanks. The generated CH₄ was almost oxidized beneath 50cm, 40cm, and 30 cm, respectively, in blocks A, B, and C, but more than half of the CH₄ was not thoroughly converted to CO₂. Therefore, using the CO₂ consuming or CO₂ generating rate to evaluate the NSZD as by some previous studies conducted would underestimate the NSZD rate when there was excessive generated CH₄ that failed to be thoroughly oxidized to CO₂.

On the other hand, even though the measured blocks were closely located, the NSZD rates varied. This could be caused by the unevenly distributed contaminants, which is commonly found at petroleum-contaminated sites [34]. Therefore, to gain a more accurate NSZD rate, around the source zone, measurements should be carried out as much as possible.

Multiple gases concentrations measurement combined with functional gene quantification would be a powerful means for distinguishing the different physicochemical pathways in NSZD. In the present study, only shallow soil gases and nucleic acid information were collected. Gas concentrations measured at different depths may produce different gradient values. However, the gained gradients are always in the same order of magnitudes [4]. Therefore, using the shallow subsurface gas concentration gradient to assess
NSZD is theoretically acceptable. The same methods can also be applied to other petroleum-contaminated sites such as oil fields, as well as petrochemical plants. To verify the proposed deductions and gain more knowledge on NSZD, deeper samples and other molecular biological analysis should be carried out in further studies.

5. Conclusions

In this study, NSZD in the vadose zone at a petroleum-hydrocarbon-contaminated site of a purification plant in Northwest China was assessed using the gradient method based on a proposed minimally invasive measurement of multiple gas concentrations. Combined with the quantification results of the *pmoA* and *mcrA* genes, the concentration of CH$_4$ was deduced as it was generated from the deep LNAPL-contaminated zone, and the methanogenesis rates were estimated to be 4 to 40 kg/a.m$^2$, which can be deemed to represent the NSZD rates. The NSZD rates were greater than those at most of the previously studied sites. The high NSZD rate at the site may be caused by ongoing leaking from the storage tanks. The generated CH$_4$ was almost oxidized before escaping into the air, but more than half of the CH$_4$ was not thoroughly converted to CO$_2$. This was different during NSZD in the middle- or late-evolution stage of the LNAPL release. Therefore, our study added new data to the NSZD rate database and updated current knowledge about NSZD, especially in China.
