Abstract: As people’s material quality of life continues to improve, water resources become subjected to varying degrees of contamination. As one of the most commonly utilised agents in water treatment, a flocculant exhibits a diverse range of forms and a vast scope of applications. However, the application of flocculants gives rise to a series of issues, including the use of large doses, the formation of sludge, the difficulty of recycling flocculants, and other concerns. The development of new flocculation technology has become a crucial step in enhancing the purification of wastewater and reducing environmental pollution. Magnetic flocculation can be classified into two main categories: magnetic seeds flocculation and magnetic flocculation. This paper presents an overview of the factors influencing magnetic flocculation, including the type of magnetic seeds, magnetic seeds particle size, and other pertinent considerations. Furthermore, the classification of magnetic flocculants in the process of magnetic flocculation is discussed. This includes the types of magnetic flocculant, namely, inorganic composite magnetic flocculants, organic composite magnetic flocculants, and biological composite magnetic flocculants. Inorganic composite magnetic flocculants are inexpensive and simple to produce; however, their dosage is considerable, and the resulting floc is not tightly formed, which impairs the efficacy of flocculation. The use of organic composite magnetic flocculants requires a smaller dosage and exhibits a strong flocculating ability; however, it may possess toxic properties and potentially cause harm to the water body. The biological composite magnetic flocculant exhibits high efficiency and no pollution, yet it is subject to stringent environmental conditions, displays poor stability, and is applicable to a relatively limited range of treatment scenarios. Furthermore, the integration of magnetic flocculation technology with other techniques is classified and summarised in diverse contexts, and the prospective research focus and direction of magnetic flocculants are proposed.

Keywords: magnetic flocculation; water treatment; magnetic seed flocculation; magnetic flocculant; combination

1. Introduction

With the rapid development of society and the continuous growth of the world population, global water resources have become particularly valuable in recent years. The Earth is 70% covered by water, but only 2.5% is freshwater, and the freshwater resources available are extremely limited. It is estimated that almost four billion people are currently experiencing water scarcity globally, with this figure potentially exceeding two billion in developing countries by 2050 [1]. The discharge of untreated wastewater from human industrial activities into natural water bodies has a detrimental impact on the environment, affecting the availability of water for plants, wildlife, and humans alike [2,3]. The conventional techniques employed for the purification of water can be broadly categorised into three principal groups: physical, chemical, and biological. Physical methods, including filtration, air flotation [4], and sand sedimentation, can be employed to target insoluble or suspended substances in water. Chemical methods, including coagulation and flocculation [5], oxidation [6], and ion exchange [7], have the potential to transform dissolved or insoluble hazardous substances into non-toxic or low-toxicity substances. The biological methods that are currently in use can be divided into two main categories: the activated
sludge method and the biofilm method. In these methods, green microorganisms are used to convert large organic molecules into smaller molecules, which can then be treated further to achieve the desired effect of water purification. While these methods can remove pollutants from water to a certain extent, they often suffer from a number of issues, including low treatment efficiency, high energy consumption, and high treatment costs.

Coagulation and flocculation represent one of the most critical and widely used surface water treatment processes for the removal of colloidal particles, phosphorus, and organic matter. The principal mechanisms of flocculation include compression of the bilayer [8], electro-neutralisation, adsorption and bridging, and netting and sweeping [9]. Flocculants act on suspended and dissolved substances in wastewater, destabilising the original colloidal particles to form flocs. These are then transformed into larger flocs through net sweeping, adsorption bridging, and so forth. Finally, the flocs are formed into sludge through sedimentation, which effectively reduces suspended solids, chromaticity, turbidity, and other indexes in the water. In order to optimise the efficiency of the treatment process, scientists have developed a range of different flocculants, including inorganic flocculants (such as aluminium salts, iron salts [10], and silicates [11]), organic flocculants (such as cationic polyacrylamide (PAM) and anionic PAM), and natural flocculants (such as humic acid and starch). Furthermore, a variety of flocculants have been combined in order to address the limitations of a single flocculant and to enhance the overall effectiveness of the treatment process. Nevertheless, it is unable to fulfil the requisite treatment requirements due to its inadequate treatment effect.

In recent years, with the continuous progress of science and technology, new coagulation and flocculation water treatment methods have emerged, among which magnetic flocculation technology has received widespread attention as a highly efficient and environmentally friendly means of water treatment. Based on magnetic seeds, magnetic flocculation enhances particle formation and accelerates the sedimentation process. Compared with conventional coagulation (CF), magnetic flocculation has the advantages of a short process, energy saving, and low cost. Magnetic flocculation can be divided into two main categories based on the method used: magnetic seed flocculation and magnetic flocculation. Figure 1a shows the magnetic seeds flocculation, which indicates that the magnetic seed and flocculant are added into the water body respectively, and the pollutants are magnetically inoculated by adsorbing the magnetic seed itself, and then the suspended particles in the water body are settled by using the effect of the applied magnetic field as well as the flocculant, so that the water body is purified. Magnetic nanoparticles can be introduced into the water body as magnetic seeds. Fe$_3$O$_4$ and Fe$_2$O$_3$ are typical magnetic nanomaterials with low toxicity, high magnetic properties, etc., and their porous structure can determine the ability to adsorb pollutants. The magnetic flocculation in Figure 1b focuses on the development of a composite magnetic flocculant with a synergistic flocculation effect, in which magnetic species are added in the preparation of the flocculant, which combine to form a modified magnetic flocculant, thereby enhancing the adsorption and settling of contaminants and separating contaminants for the purpose of purification. Magnetic particles can act as nuclei to promote the formation of settleable flocs of greater density, size, and strength [12]. The formation of larger magnetic particles—Al flocs—can be effectively removed under an applied magnetic field. The preparation of magnetic flocculants is similar to that of ordinary flocculants, using inorganic substances such as aluminium and iron salts and organic substances such as chitosan and moringa seeds. Various polymers such as polyacrylamide (PAM) [13], chitosan [14], starch [15], and alginate [16] have also been successfully grafted onto MPs and have shown high pollutant removal rates. This paper classifies magnetic flocculants into inorganic composite magnetic flocculants, organic composite magnetic flocculants, biocomposite magnetic flocculants, and other composite magnetic flocculants, and it compares their advantages and disadvantages, after first introducing the factors of external force influence on magnetic species in magnetic flocculation: force, particle size, type, and other factors. On this basis, the scenarios of magnetic flocculation in combination with other technologies are presented, and future
research priorities and directions for magnetic flocculants are suggested to provide new ideas for urban wastewater treatment. This study provides researchers with important information on the latest developments in their field of study.

2. Factors Affecting Magnetic Flocculation

2.1. External Forces on Magnetic Seed Flocculation

The influencing factors of magnetic flocculation are shown in Figure 2. The force distribution of magnetic seeds during the magnetic flocculation process is one of the key factors affecting their performance. In a magnetic field, the forces acting on magnetic particles mainly include magnetic force, gravity, hydrodynamic drag, and the interaction forces between particles [17]. Magnetic force is the force exerted by an external magnetic field on a magnetic seed, and its magnitude depends on the magnetization intensity and shape of the magnetic seed; it is usually proportional to the particle size of the magnetic seed. The influence of gravity on the volume of magnetic particles is particularly important for larger particle sizes. The hydrodynamic resistance is related to the motion state of the magnetic seed in the fluid and the flow velocity of the fluid, which affects the settling speed and efficiency of the magnetic seed. In magnetic flocculation, the magnetization of the magnetic nuclei is the basis for their functionality. The magnetization state of a magnetic seed determines its orientation and ability to migrate in the magnetic field and, thereby, influences its binding efficiency towards pollutants. The balance of forces of magnetic seeds in the magnetic field determines their trajectory in the water treatment plant, which, in turn, influences the formation and settlement of flocks. For example, when the magnetic force is greater than the hydrodynamic resistance, the magnetic seed moves quickly along the magnetic field line, which contributes to rapid flocks formation. On the contrary, if the dynamic resistance of the liquid predominates, the speed of movement of the magnetic seed slows down, which can lead to a reduction in the flocculation efficiency. In addition, the interaction forces between magnetic species, such as van der Waals forces and electrostatic forces, also play an important role in the flocculation process. These forces promote or inhibit the aggregation of magnetic species and, thereby, affect the stability and settling performance of the flocks. In practical applications, by adjusting the magnetic field strength and optimising the physical and chemical properties of magnetic seeds, the effect of these forces can be effectively controlled to achieve the best flocculation effect.
These particles were subsequently isolated from Chlorella (Chlorella sp.). It was observed that the shedding efficiency increased from 12.5% to 85% when the particle size was increased from 108 nm to 1.17 µm. The greater specific surface area of smaller magnetic particles allows for a greater number of contact points with microalgae, resulting in the formation of stronger electrostatic bonds. This increases the difficulty of dislodging smaller magnetic particles with larger particle sizes can increase the risk of system blockage and affect the long-term operational stability of processing equipment. In practical applications, magnetic nuclei with a particle size in the range of 50–200 nanometers are usually chosen. Magnetic seeds in this range can maintain good magnetic responsiveness and provide sufficient specific surface area to achieve efficient pollutant adsorption. By optimising the particle size distribution of magnetic nuclei, the removal efficiency and settling performance of magnetic flocculation technology can be significantly improved. However, some studies have shown that larger particle sizes actually have a better impact on separation efficiency. In a pioneering study, Seo et al. [18] employed (3-aminopropyl) triethoxysilane (APTES) to impart a positive charge to the initially negatively charged BaFe₁₂O₁₉ magnetic particles. These particles were subsequently isolated from Chlorella (Chlorella sp.). It was observed that the recovery of the BaFe₁₂O₁₉ magnetic particles was significantly influenced by their particle size. The shedding efficiency increased from 12.5% to 85% when the particle size was increased from 108 nm to 1.17 µm. The greater specific surface area of smaller magnetic particles allows for a greater number of contact points with microalgae, resulting in the formation of stronger electrostatic bonds. This increases the difficulty of dislodging smaller particles. Conversely, as particle size increases, the spatial arrangement and interactions of larger particles within aggregates lead to an increase in dislodgement efficiency. The enhanced dislodgement efficiency enables the efficient harvesting of chlorella and the recovery and reuse of magnetic particles.

2.3. Magnetic Species

There are different types of magnetic species, including natural magnetic minerals and artificially synthesised magnetic materials. The most commonly used magnetic materials include Fe₃O₄ (magnetite) [19], Fe₂O₃ (hematite) [20], and various ferromagnetic materials.
alloys. Different magnetic types have different magnetic properties, such as magnetization, coercivity, and stability, which directly affect the effectiveness of magnetic flocculation. For example, Fe₃O₄ has become a commonly used magnetic seed material in magnetic flocculation due to its high saturation magnetization and good chemical stability [21]. As shown in Figure 3, the mixed system is Fe₃O₄ and polymeric aluminium chloride (PAC). The magnetic seeds coated with PAC form Fe-O-Al bonds, which creates stronger structures and larger specific surface areas and strengthens the connection between the magnetic seeds and the hydrolysates of PAC [22]. In addition, Fe₂O₃ has good biocompatibility and a low cost, and it is also widely used in water treatment. Ferromagnetic alloys are used because of their special physical and chemical properties, such as high coercivity and high magnetic permeability, used in certain water treatment environments. In addition to traditional magnetic materials, researchers are also exploring new magnetic types such as magnetic nanoparticles, magnetic biochar [23], and magnetically modified natural minerals. These new magnetic species can improve their adsorption performance and selectivity and improve the removal efficiency of specific pollutants through surface modification or composite with other materials. When selecting magnetic seeds, their interaction with target pollutants, cost–benefit ratio, and environmental impact must be taken into account. For example, for waters contaminated with heavy metals, it may be necessary to choose magnetic seeds with a high adsorption capacity and good stability. To remove organic pollutants, it may be necessary to select magnetic adsorption materials with specific functional groups. By optimising the types and properties of magnetic seeds, the adaptability and treatment efficiency of magnetic flocculation technology can be improved.

![Figure 3. Mixed system of Fe₃O₄ and PAC.](image)

2.4. Other Influencing Factors

In addition to the force, particle size, and type of magnetic nuclei, there are also numerous other factors that influence the magnetic flocculation process, such as the amount of magnetic nuclei added, the stirring intensity, etc. [24]. These factors together determine the effectiveness and efficiency of magnetic flocculation. The dosage of magnetic seeds is one of the important factors affecting the magnetic flocculation effect. The dosage amount has a direct influence on the formation speed, size, and settling performance of the magnetic flocks. Insufficient dosage may result in insufficient contact between pollutants in the water and magnetic seeds, thereby reducing the efficiency of pollutant removal. On the contrary, excessive addition of magnetic nuclei can lead to the magnetic flocks becoming too large and loose, the settling time being extended, and difficulties occurring in subsequent magnetic separation processes due to the excessive amount of magnetic nuclei themselves. In addition to the aforementioned dosage, an excessively large quantity may result in flocculation, loose disintegration, and separation difficulties. However, it is also imperative to consider the dissolution of the magnetic species, such as Fe₃O₄ magnetic species. For instance, the ‘Surface Water Environmental Quality Standards’ (GB3838-2002) [25] stipulates that the iron content in water environments should not exceed 0.3 mg/L for magnetic flocculation. In the event of dissolution, the surrounding...
environment will be polluted, and the magnetic particles will become unusable. In practical applications, magnetic seed dosage needs to be optimised based on specific water quality conditions and treatment goals. In addition, the dosage of magnetic seeds is also affected by factors such as the design of the magnetic flocculation system and the efficiency of the magnetic separation equipment. Stirring intensity is another operating parameter that significantly influences the magnetic flocculation effect [26]. The stirring intensity determines the degree of uniformity of mixing magnetic seeds with pollutants in the water and thereby influences the formation of flocks and the efficiency of magnetic flocculation. Appropriate stirring intensity can promote complete contact between magnetic seeds and pollutants, accelerate the formation of flocs, and improve the sedimentation rate and water purification degree. However, excessive stirring intensity can cause the flocks formed to be dispersed, their stability to decrease, and, thus, the settling effect to be impaired. If the stirring intensity is too low, this can lead to insufficient mixing of magnetic seeds and pollutants and thus impair the flocculation effect. Therefore, it is necessary to determine the optimal stirring intensity through experiments based on specific treatment systems and water quality conditions.

3. Classification of Magnetic Flocculants

3.1. Inorganic Composite Magnetic Flocculant

Inorganic composite magnetic flocculants are obtained by compounding and reacting inorganic flocculants or flocculant materials with magnetic materials. Table 1 illustrates the complexing of inorganic compounds, namely, sodium alginate, iron, aluminium, and silicon, with magnetic particles. The majority of inorganic magnetic flocculants exhibit a removal rate exceeding 90% for turbidity, while demonstrating a comparatively lower removal rate for COD. Zhao et al. [27] employed a magnetic seed comprising natural magnetite coated with polymeric aluminium chloride (PAC) and a coating polymer, polyacrylamide (PAM), to facilitate the removal of a microalgal species, Chlorella vulgaris. The process was completed in less than 0.5 min, with 99% of the microalgal harvested. In comparison to the removal of microalgae with only Fe$_3$O$_4$ (pH: 7.0), a broader pH range was attained, with effective microalgal harvesting at pH 6.04 to 10.1 and a more extensive inclusivity of algal organisms. Ding et al. [28] prepared a polysilicate containing an iron borate and zinc sulphate (PSBFZ) flocculant and a new magnetic flocculant PSBFZ-Fe$_3$O$_4$ for the treatment of aqueous ink wastewater. The turbidity removal and decolourisation rate of PSBFZ-Fe$_3$O$_4$ at room temperature can reach 96% and 97%, respectively, which represents an increase of 3% and 2% in comparison to the removal rates achieved by PSBFZ alone. Furthermore, the flocculation waste can be recycled on two occasions through the utilisation of a magnetic recovery process, which can be readily separated from the wastewater. This facilitates the potential reuse of the magnetic flocculant. The magnetically recycled PSBFZ-Fe$_3$O$_4$ flocculant can be reused by adding a small amount of PSBFZ, and its removal rate of turbidity and chromaticity of wastewater can still reach more than 95%. However, it is not an effective method for degrading COD; thus, it requires combination with a variety of treatment techniques, including physical, chemical, and biological methods, in order to achieve a more comprehensive pollutant removal. Dai et al. [29] combined the environmental properties of calcium-based flocculants with the convenience of magnetic flocculation through a simple composite method to prepare Ca(OH)$_2$/Fe$_3$O$_4$ magnetic flocculants for efficient flocculation of black liquor lignin in papermaking. This flocculant can be used directly in aqueous sodium lignin solution without pH neutralisation and maintains a high lignin removal rate of 91% to 95% in the pH range of 9 to 12.5. In addition, the flocculant has a high tolerance to salts (0–1 mol/L NaCl) and pH values (9–12.5). Due to the magnetic properties of Fe$_3$O$_4$, the flocculant Ca(OH)$_2$/Fe$_3$O$_4$ can aggregate quickly under the influence of an external magnetic field. This magnetically controlled aggregation facilitates the contact and binding of lignin molecules with flocculants, thereby improving flocculation efficiency. After the flocculation process is complete, the flocks formed can be quickly separated by an external magnetic field. Due to the superparamagnetic property of
Ca(OH)$_2$/Fe$_3$O$_4$ flocculants, the flocs settle quickly under the effect of a magnetic field, making the separation process between flocks and aqueous solutions more efficient and faster. Inorganic composite flocculants mainly rely on van der Waals forces due to the interaction between their inorganic components and magnetic particles, which are relatively weak and not as strong as chemical bonds. This means that the flocs formed during the flocculation process may not be stable enough and may easily separate from the magnetic particles during the treatment process, weakening the magnetic responsiveness of the magnetic flocculant, affecting the flocculation effect and subsequent magnetic separation efficiency.

3.2. Organic Composite Magnetic Flocculant

Composite organic flocculants are prepared by crosslinking and polymerizing high-molecular-weight organic compounds, such as chitosan, starch, cellulose, polyacrylamide,
etc., with magnetic materials. They combine the flocculation properties of organic polymers and the magnetic properties of magnetic nanoparticles to efficiently remove pollutants from water. They have a high intrinsic viscosity and good flocculation properties. Examples of organic compounds that can be used for compounding with magnetic particles include chitosan, moringa seeds, and other seeds, as illustrated in Table 2. Hena et al. [36] first dispersed Fe$_3$O$_4$ nanoparticles in deionized water and achieved better dispersion by ultrasonic treatment. Then, FeCl$_3$ was added as an oxidizing agent to the solution and stirred continuously at room temperature. Next, pyrrole monomer (Py) was added and the reaction mixture was stirred at room temperature for 2.5 h. Finally, the reaction was stopped by adding acetone, and the resulting nanocomposite material was purified by filtration and washing. The flocculant achieved a recovery efficiency of nearly 99%, 92.4%, and 90.8% for the microalgae Botryococcus braunii, Chlorella protothecoides, and Chlorella vulgaris, respectively. In the study by Xie et al. [37], self-made magnetic Fe$_3$O$_4$, self-made magnetic sodium silicate, Al$_2$(SO$_4$)$_3$, MgSO$_4$, and starch were used to prepare magnetic organic loaded Fe$_3$O$_4$-PSAM St flocculants through a series of chemical reactions and treatment steps. The experimental results showed that under the optimal conditions (Fe$_3$O$_4$-PSAM St addition amount of 40 mg/L, simulated wastewater pH of 5–12, flocculation time of 10 min, settling time of 10 min), the highest removal rate of Congo red could be achieved (95.0%). After six repeated flocculation trials using 50% (w/w) magnetic flocs and 50% (w/w) Fe$_3$O$_4$-PSAM St as flocculants, the removal rate of Congo red still reached about 93%, showing good reusability and stability. Reck et al. [38] employed the natural material moringa seed protein in conjunction with iron oxide nanoparticle technology for the treatment of aqueous solutions containing synthetic dyes. The application of a magnetic field during the precipitation process resulted in a notable acceleration of the precipitation rate and an enhanced removal efficiency of the dyes. For instance, the removal of cochineal dye increased from 45% to 86% with the utilization of a magnetic field, while the removal of sunset yellow increased from 15% to 69%. Furthermore, the removal of reactive black 5 and bright blue achieved 94% and 52%, respectively. Furthermore, the article indicated that the optimal protein concentration differed for various dyes, with 150 mg/L for cochineal and sunset yellow, 115 mg/L for reactive black 5, and 75 mg/L for brilliant blue. This approach not only eliminates hazardous dyes from industrial wastewater but also enhances the removal efficiency by optimising the flocculation conditions (e.g., protein concentration, pH, and application of the magnetic field). There are various types of organic polymer compounds, and the properties of flocculants can be customized through various synthesis methods and modification techniques to meet the needs of different wastewater treatments. Due to the stronger bonding effects such as coordination bonds that can form between organic and inorganic polymer components, magnetic particles are less likely to detach from the flocks during the flocculation process, improving the stability of the flocks. But the high costs are also a factor to consider.

### 3.3. Biological Composite Magnetic Flocculant

A biological compound magnetic flocculant is a special type of flocculant that combines biologically generated flocculants with magnetic materials. This flocculant combines biopolymers produced by organisms with magnetic particles to enhance the flocculation effect and facilitate magnetic separation. Guo et al. [44] used chemical reagents such as chitosan, isopropanol, chloroacetic acid, and activated sludge as microbial flocculant MBFX-8 in their study. Magnetic properties were prepared by chemical modification and a co-precipitation method. Fe₃O₄@carboxymethyl chitosan (CMC) nanoparticles were
prepared, and MBFX-8 was prepared through freezing centrifugation and other steps. The production of composite flocculants involved the combination of MBFX-8 with magnetism Fe$_3$O$_4$@CMC. The mixture was performed according to different mass ratios, and stirring and static reactions were carried out. The results showed that under certain conditions (pH 6.5, flocculant dosage 5 g/L, standing reaction time 3 h), the removal rate of Cu$^{2+}$ by the composite flocculant reached 98.9%. Yu et al. [45] synthesised the composite cellulose@iron oxide nanoparticles containing magnetic nanoparticles and cellulose by a one-step co-precipitation method. The cellulose was dissolved using an aqueous NaOH–thiourea–urea solution. The NaOH was used as a precipitant for iron oxide nanoparticles in the cellulose solution. Additionally, low-cost cellulose was used as a template to promote the growth of the nanoparticles in the cellulose matrix. The results of Langmuir adsorption isotherm modelling demonstrated that the adsorption capacities of the complexes for arsenite and arsenate were 23.16 and 32.11 mg/g, respectively. The Fe$_2$O$_3$ nanoparticles were uniformly dispersed in the cellulose matrix. The composite exhibited a sensitive magnetic response and superparamagnetic behaviour, which enabled its easy separation from the aqueous solution by an external magnetic field. This property is of great significance for flocculant recycling and reuse in practical water treatment processes. In a study conducted by Periyasamy et al. [46], environmentally friendly materials, including cellulose (Cel), hydrotalcite (HT), and hydroxyapatite (HAp), were used to prepare cellulose/hydrotalcite (Fe$_3$O$_4$@CelHT) and cellulose/hydroxyapatite (Fe$_3$O$_4$@CelHAp) for the removal of Cr(VI). The biocomposite magnetic flocculant combines the rapid settling properties of magnetic materials with the flocculation effect of biopolymers while being biodegradable and environmentally friendly. Due to these properties, biocomposite magnetic flocculants have enormous potential and research value in the field of water treatment. Due to its biodegradability, the impact of biomagnetic flocculants on the environment is relatively low. However, stability problems may arise with biological magnetic flocculants under certain conditions, such as pH changes or reduced flocculation efficiency in high-temperature environments. Compared to inorganic magnetic flocculants, the manufacturing process of biological magnetic flocculants may be more complex and require precise biotechnological operations.

### 3.4. Advantages and Disadvantages of Composite Magnetic Flocculants

Magnetic flocculants are classified into three categories based on their composition, namely, inorganic, organic, and biological. Each category exhibits distinct characteristics. Inorganic composite magnetic flocculants are renowned for their affordability, yet they may exhibit inadequate biocompatibility and an elevated risk of environmental accumulation. Organic composite magnetic flocculants are diverse and adjustable, and they can be chemically structured to meet specific needs. However, they are more costly and complex to synthesise, and excessive amounts of some organics may be harmful to water bodies [47]. Biocomposite magnetic flocculants are distinguished by their exemplary environmental compatibility and biocompatibility, derived from renewable resources and readily biodegradable. However, they are associated with elevated production costs and process complexity, as well as more rigorous environmental standards. In practice, the combination of different types allows for the optimisation of the overall performance of the flocculant, thereby achieving more efficient water treatment. Specific advantages and disadvantages are shown in Table 3.

4. Magnetic Flocculation Combined with Other Technologies

Magnetic flocculation technology, as an efficient physical and chemical water treatment method, is based on utilizing the magnetic properties of magnetic particles to enhance the flocculation process, thereby improving the removal efficiency of suspended solids, colloidal particles, and certain dissolved pollutants in water. This technology promotes the coagulation and sedimentation of pollutants by adding magnetic nuclei or magnetic flocculants into the treatment system, thus achieving rapid separation. Magnetic flocculation technology has been widely studied and used in the field of water treatment due to its high efficiency, low cost, and easy operation. In order to further improve the efficiency and adaptability of treatment, magnetic flocculation technology has been widely combined with other water treatment technologies in recent years, creating various comprehensive treatment processes. The majority of the co-located technologies presented in Table 4 are employed in the deep treatment stage, or in the pre-treatment stage, with varying degrees of phosphorus removal in both domestic wastewater and industrial wastewater.

In a study conducted by Liu et al. [51], a magnetic composite flocculant (MFPFS) was used, which was compounded with Fe₃O₄ nanoparticles and polymeric ferric sulphate (PFS). The results demonstrated that the flocculant was capable of achieving COD and chromaticity removals of up to 60% and 80%, respectively. Furthermore, the combination with sulphate radical oxidation technology effectively removed the residual pollutants following flocculation of MFPFS through Fe²⁺-activated sulphate radical oxidation, significantly enhancing the removal rates of COD and chroma, which could be further increased to 75% and 95%, respectively. The efficacy of sulphate radical oxidation in treating recalcitrant organics was demonstrated. This combined approach not only enhanced the removal of organic matter but also improved the overall water treatment performance. Wang et al. [52] employed magnetic flocculation with response surface methodology (RSM) and artificial neural network (ANN) to optimise the magnetic flocculation process for the treatment of secondary effluent from municipal wastewater plants. Among the methodologies employed, Response Surface Methodology (RSM) was utilised, specifically the Box–Behnken Design (BBD), for the design of experiments. The concentrations of polymeric aluminium chloride (PAC), magnetic powder (Fe₃O₄), and flocculant (PAM) were selected as the controllable variables, with total phosphorus (TP) removal and turbidity removal employed as the responses to determine the optimal combination of the concentrations of PAC, magnetic powder, and PAM by RSM. A three-layer BP-ANN model was constructed using MATLAB
software and the back-propagation (BP) algorithm for the artificial neural network (ANN). The input layer comprised the concentrations of PAC, magnetic powder and PAM, while the output layer represented the removal rate of TP and turbidity. The TP and turbidity removal rates obtained experimentally under the optimal conditions determined by RSM were 88.79% ± 5.45% and 63.48% ± 9.60%, respectively. The combination of multiple models may prove a superior approach to the adaptation of the process to the inevitable variation of variables that will occur in the actual water treatment process.

5. Conclusions and Perspectives

This article discusses the application and potential of magnetic flocculation technology in the field of water treatment. Magnetic flocculation in the field of water treatment can be divided into magnetic seed flocculation and magnetic flocculation. Magnetic seed particles are used to promote flocculation. Factors affecting magnetic seed flocculation include force, particle size, type, dosage, and agitation speed. The flocculation trajectory of magnetic species is influenced by magnetic force, gravity, van der Waals force, and electrostatic force. The classification and characteristic analysis of magnetic flocculants further expand our understanding of magnetic flocculation technology. There are other examples such as carbon loading and ultrafiltration. These combined-technology examples demonstrate the flexibility and effectiveness of magnetic flocculation in integrated water treatment solutions. Magnetic flocculation technology has shown great application prospects in the field of water treatment due to its high efficiency and environmental protection. Future research
should further address the renewal and expansion of magnetic species, the development of new magnetic materials, the optimisation of flocculant synthesis methods, and the improvement of synergies with other technologies to achieve broader applications and more profound improvements in water quality.

The potential of magnetic seeds and magnetic flocculants for application in water treatment technology is considerable, with several avenues of development emerging from this research. The initial focus of research will be on the multifunctionality of these materials. The precise control of the size, morphology, and magnetic properties of magnetic materials using nanotechnology will optimise their performance in specific applications. Furthermore, the introduction of intelligent response functions may enable the materials to automatically adjust their treatment strategies according to changes in the environment. Additionally, the incorporation of flocculation, adsorption, and catalytic properties may facilitate the highly efficient removal of a wide range of pollutants in a complex water environment. Secondly, the combination of magnetic materials with inorganic materials, organic polymers, or biological materials will become a focus of innovation, with the objective of enhancing the efficiency and selectivity of removal. The achievement of large-scale production and cost reduction of magnetic materials, with the aim of making them more widely used in practical water treatment projects, in addition to the development of non-toxic and recyclable magnetic materials, will become a trend in order to reduce the impact on the environment. Ultimately, future research should further investigate the renewal and expansion of magnetic species, the development of new magnetic materials, the optimisation of flocculant synthesis methods, and the enhancement of synergistic effects with other technologies. This will facilitate the achievement of wider applications and deeper water quality improvements.
