Abstract: Phase relations of the Fe–Cr–Er system in the temperature range 973–1273 K were experimentally investigated using equilibrated alloys. The isothermal sections consisted of 9 single-phase regions, 16 two-phase regions, and 8 three-phase regions at 973 K and 1073 K. At 1273 K, the σ phase disappeared, and liquid appeared. All single phases had a solid solubility range that showed a downward trend with a decrease in temperature. The homogeneity range of the $ErFe_{12-x}Cr_x$ ternary compound was determined to be x = 1.8–4.5. The more accurate phase relations obtained in this work can better guide the preparation of Fe–Cr–Er alloys in actual production.

1. Introduction

Oxide dispersion-strengthened (ODS) steel, which developed from martensitic and ferritic steels, is the most promising candidate for nuclear reaction cladding [1]. ODS steel is strengthened by dispersing oxide particles, which strongly impede dislocation motion and thereby increase the onset stress of plastic deformation and creep resistance [2,3]. ODS ferritic/martensitic steels containing 9–12 mass% Cr have been developed as fuel cladding material because of their high creep strength at elevated temperatures and adequate resistance to neutron irradiation embrittlement [4–9]. The performance of ODS steel largely depends on the particle size and stability of the dispersed oxide nanoparticles [10,11]. Oxide particles containing rare earth elements, especially Y2O3, are the most widely used; however, the concentration of oxide particles containing Y is readily saturated in ODS steel [12]. To further increase the concentration of oxide particles to improve the material properties, it is necessary to add other rare earth elements. Er not only forms oxide particles but can also form magnetic intermetallic compounds with transition metals, which can play a magnetic refrigeration role and prevent the reactor from overheating and causing accidents [13–20]. Therefore, ODS steel containing the Fe–Cr–Er system is a potential nuclear reactor cladding material.

To study the Fe–Cr–Er system, it is very important to know the thermodynamic information of the ternary system. Phase diagrams are an effective means to intuitively express the relationship between phases in a thermodynamic equilibrium state and are the basic theoretical guidance for the research, development, and design of new materials [21–26]. However, the phase diagram information of the Fe–Cr–Er ternary system is still lacking. Only Pan et al. [27] measured its isothermal section at 773 K in 2014. The chemical composition and phase content of multi-component iron-based alloys at different temperatures directly affect macroscopic properties of the material [28–30]. Considering that the nuclear reactor is operated at high temperatures, only studying 773 K is far from practical. Therefore, the isothermal section of the Fe–Cr–Er ternary system needs to be completed. In this work, the isothermal sections of the Fe–Cr–Er ternary system at 1273 K, 1073 K, and 973 K were determined by the equilibrium alloy method.

The Fe–Cr binary system has been extensively studied as the basis for the study of many engineering materials [31–34]. The σ phase is the most prominent characteristic phase in

the Fe–Cr binary system. Menezes et al. [35] found the existence of the σ phase by X-ray diffraction (XRD) characterization. Bergman et al. [36] analyzed the crystal structure of the σ phase. Andersson et al. [37] performed the first thermodynamic evaluation of the Fe–Cr system. Based on Andersson's work, Lee [34] modified the model of the liquid phase and improved the Fe–Cr phase diagram. Xiong et al. [38] provided a comprehensive summary of thermodynamic calculations for the Fe–Cr system and updated descriptions concerning the miscibility gap band, Curie temperature, and magnetic moment. Jacob et al. [31] adopted first-principles calculations to re-select the σ phase model and further optimized the Fe–Cr phase diagram, as shown in Figure 1.

Figure 1. The calculated Fe–Cr phase diagram based on the work of Jacob et al. [31].

There are four compounds (ErFe$_2$, ErFe$_3$, Er$_6$Fe$_{23}$, and Er$_2$Fe$_{17}$) in the Fe–Er binary system. Meyer [39] obtained the Fe–Er binary phase diagram by thermal analysis, electron probe microanalysis (EPMA), and XRD. Buschow and Goot [40] studied the phase relationship, crystal structure, magnetic properties, and lattice constants of various intermetallic compounds in the Fe–Er system and noticed that Fe and Er show mutual solubility. The Miedema model was employed to calculate the enthalpy of the formation of an intermetallic compound in the Fe–Er system [41]. Recently, Zhou et al. [42] conducted a detailed thermodynamic evaluation of the Fe–Er system, as shown in Figure 2.

Figure 2. The calculated Er-Fe phase diagram based on the work of Zhou et al. [42].

No intermetallic compounds in the Cr–Er binary system have been reported. The calculated phase diagram used in this work adopted the latest thermodynamic parameters reported by Ray et al. [43] in 1996, as shown in Figure 3.

Figure 3. The calculated Cr–Er phase diagram based on the work of Ray et al. [43].

In the Fe–Cr–Er ternary system, it is generally believed that there are two types of intermetallic compounds: $ErCr_{12-x}Fe_x$ and $Er_3Cr_{29-x}Fe_x$ [44,45]. Stefanski et al. [46] identified $ErCr_2Fe_{10}$ and studied its structure. On this basis, Bara [47] further discussed the magnetic properties of $ErCr_2Fe_{10}$. Luo [48] synthesized a series of $Er_3Cr_{29-x}Fe_x$ compounds to investigate their structures and magnetic properties by XRD and magnetic measurements. Luo [48] found that all $Er_3Cr_{29-x}Fe_x$ compounds crystallized in disordered Th_2Ni_{17}-type structures. By combining the three related binary phase diagrams, Pan et al. [27] measured an isothermal section of the Fe–Cr–Er ternary phase diagram and analyzed the relationship between different phases at 773 K, as shown in Figure 4. Previously reported binary and ternary phases, crystal structures, and lattice parameters are listed in Table 1.

2. Materials and Methods

The equilibrium alloy method of static measurement was adopted in this work. Iron rod (99.99 mass%), chromium rod (99.99 mass%), and erbium block (99.99 mass%) were selected as raw materials. Considering the high density of Er, the mass of each alloy sample was designed to be 18 g. The compositions of each alloy are listed in Tables 2–4. To prevent the alloy samples from being oxidized, sponge titanium was used as an oxygen absorbent in the arc-melting process. Each sample was melted on a water-cooled copper crucible under a high-purity argon atmosphere. To ensure homogeneity, each sample was remelted at least six times. The prepared alloy samples were sealed in quartz tubes filled with argon as a protective gas and annealed at 973 K and 1073 K for 90 days and at 1273 K for 60 days. After annealing, the alloys were quenched in ice water to retain the high-temperature microstructure.

EPMA (JAXA-8800 R, JEOL, 15 kV, 1×10^{-8} A, Tokyo, Japan) equipped with an OXFORD INCA 500 wave-dispersive X-ray spectrometer (WDS, JAXA-8800 R, JEOL, 15 kV, 1×10^{-8} A, Tokyo, Japan) was used to detect the microstructure of equilibrated alloys and composition of each phase, including solubility. XRD (Rigaku d-max/2550 VB, Cu K, 40 kV, 250 mA, Tokyo, Japan) was employed to analyze the crystal structure of typical alloys within the scanning range of 10°–90° and speed of 0.133°/s. The data were analyzed by JADE 8.7 software. Backscattered electron (BSE) images of the alloy samples were acquired using a scanning electron microscope (SEM; TESCAN MIRA3 LMH, 15 kV, working distance of 15 mm, Brno, Czech Republic).

3. Results

The isothermal section of the Fe–Cr–Er system at 1273 K was obtained based on the analysis of typical alloy samples at 1273 K. The maximum solid solution solubilities of Cr were 15.19 at.%, 2.46 at.%, 18.67 at.%, and 18.89 at.% in $ErFe_2$, $ErFe_3$, Er_6Fe_{23}, and Er_2Fe_{17}, respectively. Only $ErCr_2Fe_{10}$ was found as a ternary compound at this temperature and could dissolve about 20.43 at.% Cr at most. In addition to the solution of Cr mentioned above, this work found that Er also can dissolve as $ErFe_2$, $ErFe_3$, Er_6Fe_{23}, and Er_2Fe_{17}. This is a clear difference from the results of Pan et al. [27]. This phenomenon may be due to the influence of the experimental temperature. The Fe–Er binary phase diagram also showed no solid solubility of Er in Fe–Er binary compounds. After repeatedly confirming the accuracy of the experimental data, we speculate that the addition of Cr may affect the solubility of Er in Fe–Er binary compounds. Comparison between this work and published

literature [31,39,43] shows that the phase relationships are accurate, except that solubility differs slightly in the relevant binary phase diagrams. This confirmed the reliability of the Fe–Cr–Er isothermal section at 1273 K, shown in Figure 5.
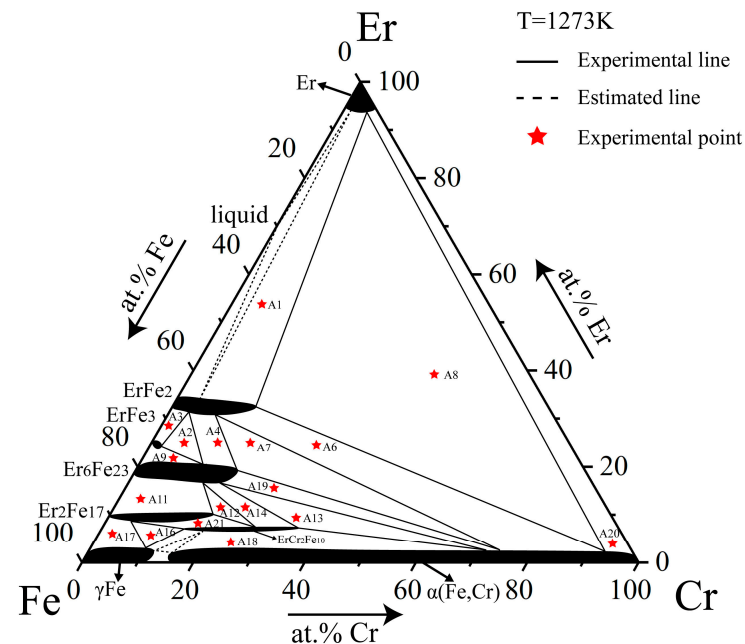

Figure 5. Isothermal section of the Fe–Cr–Er ternary system at 1273 K determined in this work.

The isothermal section of the Fe–Cr–Er ternary system at 1073 K is similar to that at 1273 K, except that the maximum solid solubilities of $ErCr_2Fe_{10}$, $ErFe_2$, $ErFe_3$, Er_6Fe_{23}, Er_2Fe_{17}, and Er are slightly lower. Additionally, $\alpha(Fe,Cr)$ appears at the Fe-enriched corner instead of $\gamma(Fe)$ at 1073 K. This is consistent with the binary optimized phase diagram, and therefore its appearance is reasonable and in accordance with expectation [31]. The 1073 K isothermal section obtained in this work is shown in Figure 6.
Figure 6. Isothermal section of the Fe–Cr–Er ternary system at 1073 K obtained in this work.

The isothermal section of the Fe–Cr–Er ternary system at 973 K was determined based on phase equilibrium data for 13 alloy samples at 973 K, as shown in Figure 7. Eight three-phase regions and 16 two-phase regions were measured. In this isothermal section, there was only one ternary compound, $ErCr_2Fe_{10}$, and four binary compounds, all having a solid solubility interval. In the region with low Er content, Fe and Cr also formed α(Fe, Cr). The solid solution range of all compounds in this system became narrower than that at 1073 K, so it can be speculated that the solid solution range narrowed as the temperature decreased.
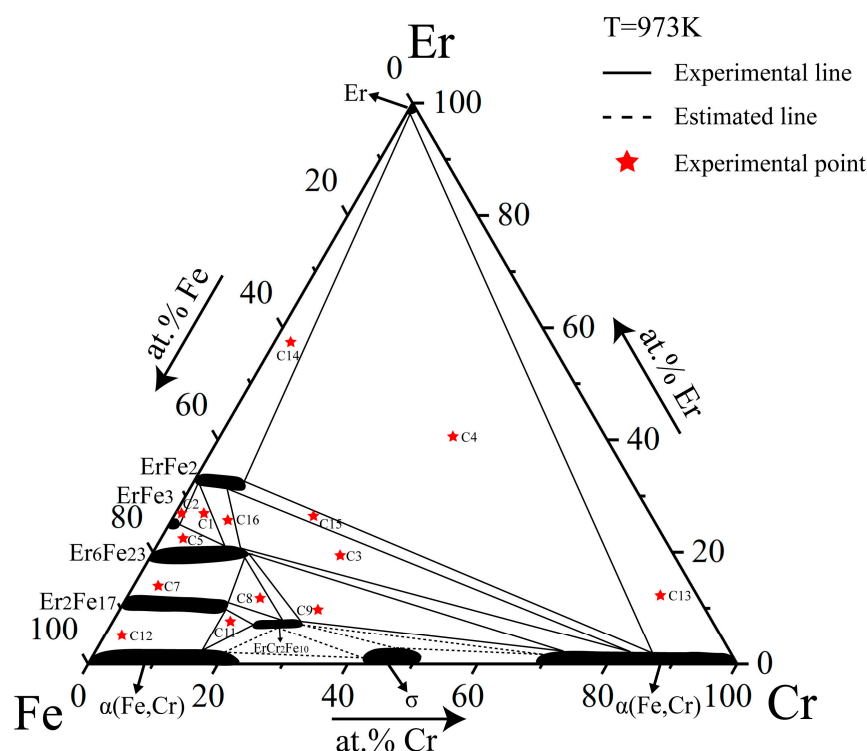

Figure 7. Isothermal section of the Fe–Cr–Er ternary system at 973 K obtained in this work.

4. Discussion

The experimental data obtained from SEM, EPMA, and XRD examination were analyzed to determine the isothermal sections and phase relationships of the Fe–Cr–Er ternary system at 1273 K, 1073 K, and 973 K. In the following context, the phase relations in several key alloys are discussed in detail.

4.1. Phase Equilibria at 1273 K

Twenty alloy samples were prepared to determine the isothermal section and phase relationships of the Fe–Cr–Er ternary system at 1273 K. The constituent phases of each alloy sample are listed in Table 2. The nominal composition was set before synthesizing each alloy, and the content of each element in each phase was measured by WDS.

Figure 8 presents BSE images and XRD patterns of alloys A2 and A7 annealed at 1273 K. From the observed phase distribution in Figure 8a, there were three different phases in A2. Analysis of the X-ray diffraction pattern in Figure 8b indicated that the phase composition of A2 was the three-phase equilibrium of $ErFe_2$ + $ErFe_3$ + Er_6Fe_{23}. WDS further showed Cr concentrations of 11.73 at.%, 1.72 at.%, and 3.56 at.% in Er_6Fe_{23}, $ErFe_3$, and $ErFe_2$, respectively. Compared with alloy A2, shown in Figure 8c,d, it was determined that alloy A7 was located in the three-phase equilibrium region of ErFe2 + α(Fe,Cr) + Er_6Fe_{23}. The WDS results further showed solid solubilities of Cr in Er_6Fe_{23} and $ErFe_2$ of 18.34 at.% and 6.94 at.%, respectively. These two phases can dissolve each other to a large extent between Fe and Cr, which is considered a reasonable phenomenon from the speculation of the Fe–Cr phase diagram.
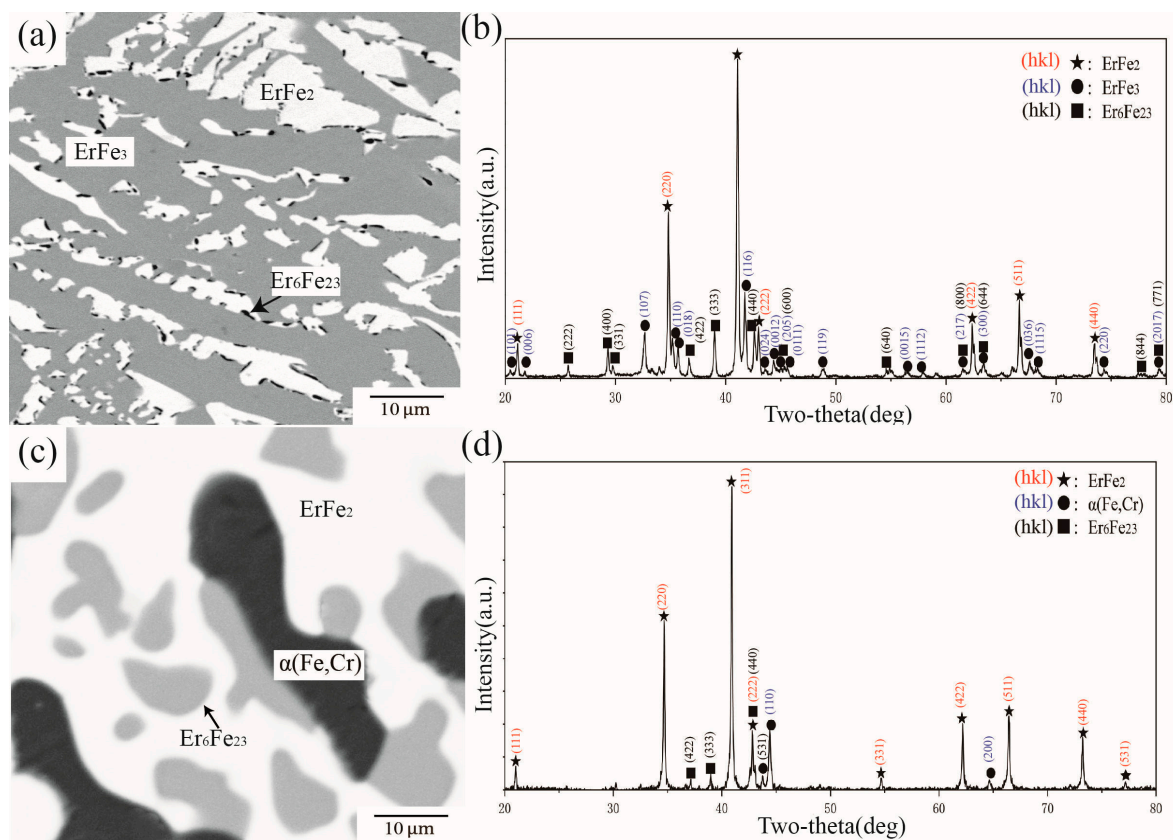

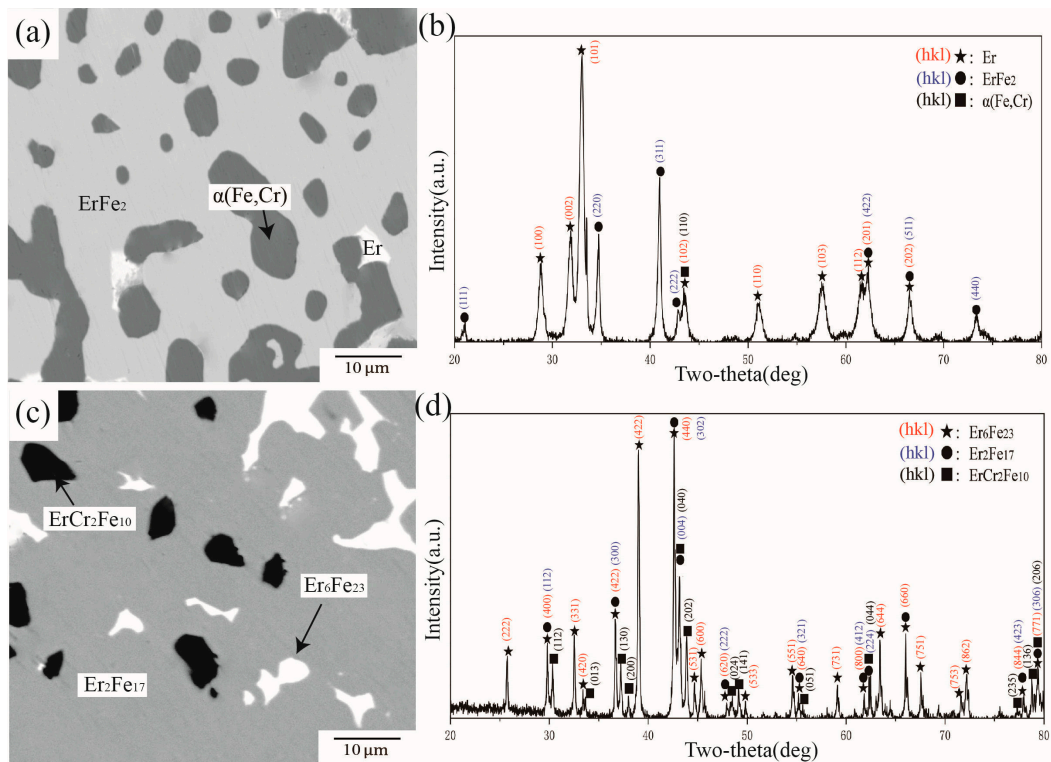

Figure 8. (**a**) BSE image of alloy A2, (**b**) XRD result of alloy A2, (**c**) BSE image of alloy A7, (**d**) XRD result of alloy A7.

BSE images and XRD patterns of alloys A8 and A12 are shown in Figure 9. Figure 9a illustrates the phase composition in alloy A8, which comprises three phases. By comparing standard powder diffraction file (PDF) cards with the diffraction peaks in Figure 9b, it was concluded that A8 was located in a three-phase equilibrium of $ErFe_2$ + Er + $\alpha(Fe,Cr)$. The WDS results further showed approximately 14.80 at.% Cr dissolved in $ErFe2$. Combined with information extracted from XRD, the black area in Figure 9c was identified as the ternary intermetallic compound $ErCr_2Fe_{10}$. The other two phases with different contrasts are Er_2Fe_{17} and Er_6Fe_{23}. The WDS results further showed approximately 13.46 at.% Cr dissolved in Er_6Fe_{23} and 18.32 at.% Cr in Er_2Fe_{17}. As the solitary ternary compound in this system, $ErCr_2Fe_{10}$ dissolved more Cr and had a certain width in the direction of Er in this work compared with that of Pan et al. [27].

BSE images and XRD patterns of alloys A13 and A16 are shown in Figure 10. Figure 10a illustrates the phase composition of alloy A13, which comprises three phases. According to the analysis of characteristic peak positions in Figure 10b, $ErCr_2Fe_{10}$, Er_6Fe_{23}, and $\alpha(Fe,Cr)$ were determined in A13 and formed a three-phase equilibrium. WDS further determined that approximately 16.75 at.% and 11.90 at.% Cr were dissolved in Er_6Fe_{23} and $ErCr_2Fe_{10}$, respectively. Figure 10c,d show BSE images and XRD patterns of A16. Although there is only one characteristic peak of $\gamma(Fe)$ in the 2θ range from 20° to 80°, the peak exists independently. By combining the law of phase equilibrium and the Fe–Cr phase diagram, A16 was defined in the three-phase area of Er_2Fe_{17} + $ErCr_2Fe_{10}$ + $\gamma(Fe)$. According to WDS data, the maximum atomic percentage of Cr in $\gamma(Fe)$ was 10.02 at 1273 K in A16. The solubility of Cr in $\gamma(Fe)$ conforms to the description of Jacob et al. [31].

4.2. Phase Equilibria at 1073 K

Fourteen alloy samples were prepared to determine the isothermal section and phase relationships of the Fe–Cr–Er ternary system at 1073 K. The constituent phases of each alloy sample are listed in Table 3.

Both B1 and B2 had three phases based on the BSE images (Figure 11a,c). According to the XRD and WDS results, all phases are already identified. B1 and B2 are located in three-phase equilibria of $ErFe_2$ + Er_6Fe_{23} + $ErFe_3$ and $ErFe_2$ + Er_6Fe_{23} + α(Fe,Cr), respectively. Cr was present at 13.49 at.% and 14.85 at.% in the compound Er_6Fe_{23} in B1 and B2. There was less than 18.67 at.% Cr, which is the maximum solid solution solubility of Cr at 1273 K. As the temperature decreased by 200 K, the solid solubility of Cr in Er_6Fe_{23} showed a significant declining trend.

**Figure 11.** (**a**) BSE image of alloy B1, (**b**) XRD result of alloy B1, (**c**) BSE image of alloy B2, (**d**) XRD result of alloy B2.

BSE images of alloy samples B8 and B11 are shown in Figure 12a,c. The gray phase in B8 and dark gray phase in B11 have the same atomic ratios of ErCr2Fe10, and the XRD characteristic peaks of $ErCr_2Fe_{10}$ (shown in Figure 12b,d) are basically consistent with the PDF card of the known compound, $ErCr_2Fe_{10}$. To sum up, $ErCr_2Fe_{10}$ does not disappear with the decrease in temperature and is a phase that can exist stably at low temperatures. Noticeably, γ(Fe) was replaced by α(Fe,Cr) in the Fe-enriched corner. This is reasonable and consistent with the Fe–Cr phase diagram.

Figure 13 shows BSE images and XRD patterns of alloys B3 and B7. By combining the data shown in Figure 13a,b, the $ErFe_2$, Er, and α(Fe,Cr) phases were found in B3, indicating a three-phase equilibrium of $ErFe_2$ + Er + α(Fe,Cr). The WDS results further validate these phases and indicate a solid solubility of Cr of 10.48 at.% in $ErFe_2$. In Figure 13a, the

uniform distribution of Er in the area also proved that it precipitated in a later stage. This can be used to judge whether the sample was in equilibrium. Compared with alloy B3, shown in Figure 13c,d, it can be determined that alloy B7 was located in the three-phase equilibrium region of Er_2Fe_{17} + Er_6Fe_{23} + $ErCr_2Fe_{10}$. The WDS results further showed that approximately 8.35 at.% Cr was dissolved in Er_6Fe_{23} and approximately 17.77 at.% of Cr was dissolved in Er_2Fe_{17}.

Figure 12. (**a**) BSE image of alloy B8, (**b**) XRD result of alloy B8, (**c**) BSE image of alloy B11, (**d**) XRD result of alloy B11.

4.3. Phase Equilibria at 973 K

Thirteen alloy samples were prepared to determine the isothermal section and phase relationships of the Fe–Cr–Er ternary system at 973 K. The constituent phases of each alloy sample are listed in Table 4.

There are three obvious contrasts in the BSE images of alloy samples C4 and C8, as shown in Figure 14a,c. By comparing standard PDF cards and the characteristic peaks in Figure 14b,d, C4 and C8 belong to the three-phase equilibria $ErFe_2$ + Er + $\alpha(Fe,Cr)$ and Er_2Fe_{17} + Er_6Fe_{23} + $ErCr_2Fe_{10}$, respectively. By analyzing WDS data, the maximum solid solubilities of Cr in $ErFe_2$ and Er_2Fe_{17} were 7.50 at.% and 16.23 at.%, respectively. The solubility of Cr in Fe–Er binary compounds was significantly reduced compared with that at 1073 K and 1273 K.
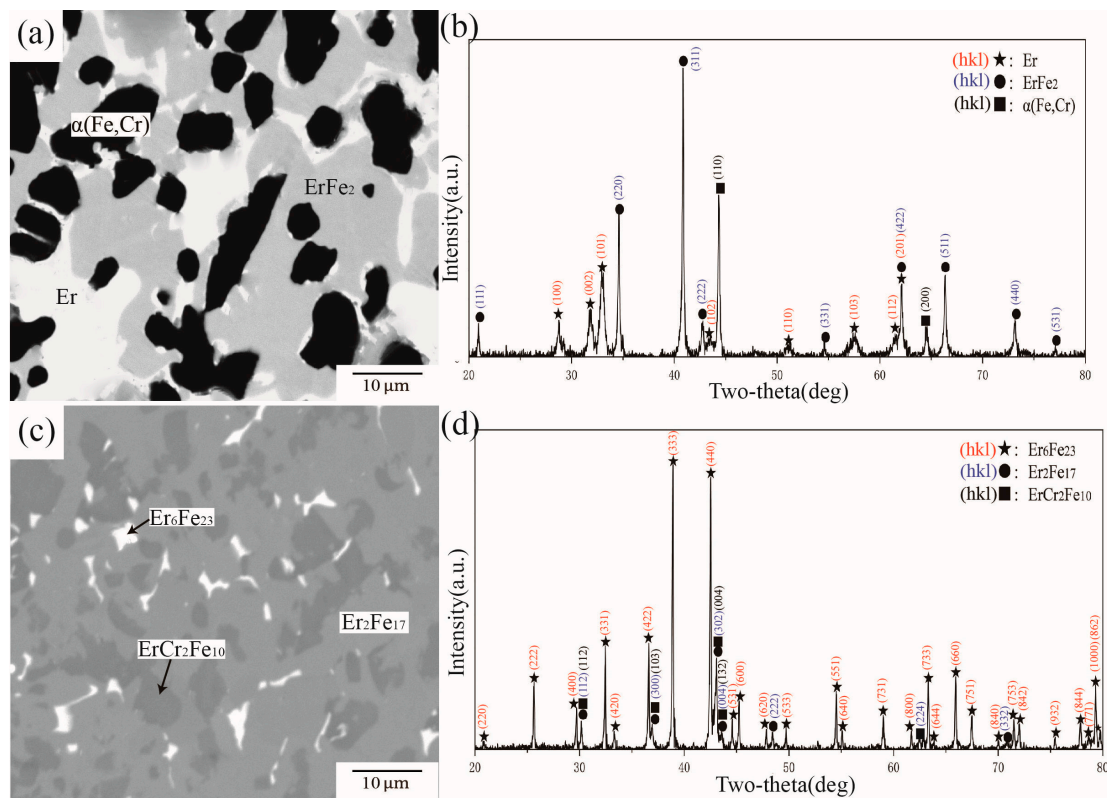

Figure 13. (**a**) BSE image of alloy B3, (**b**) XRD result of alloy B3, (**c**) BSE image of alloy B7, (**d**) XRD result of alloy B7.
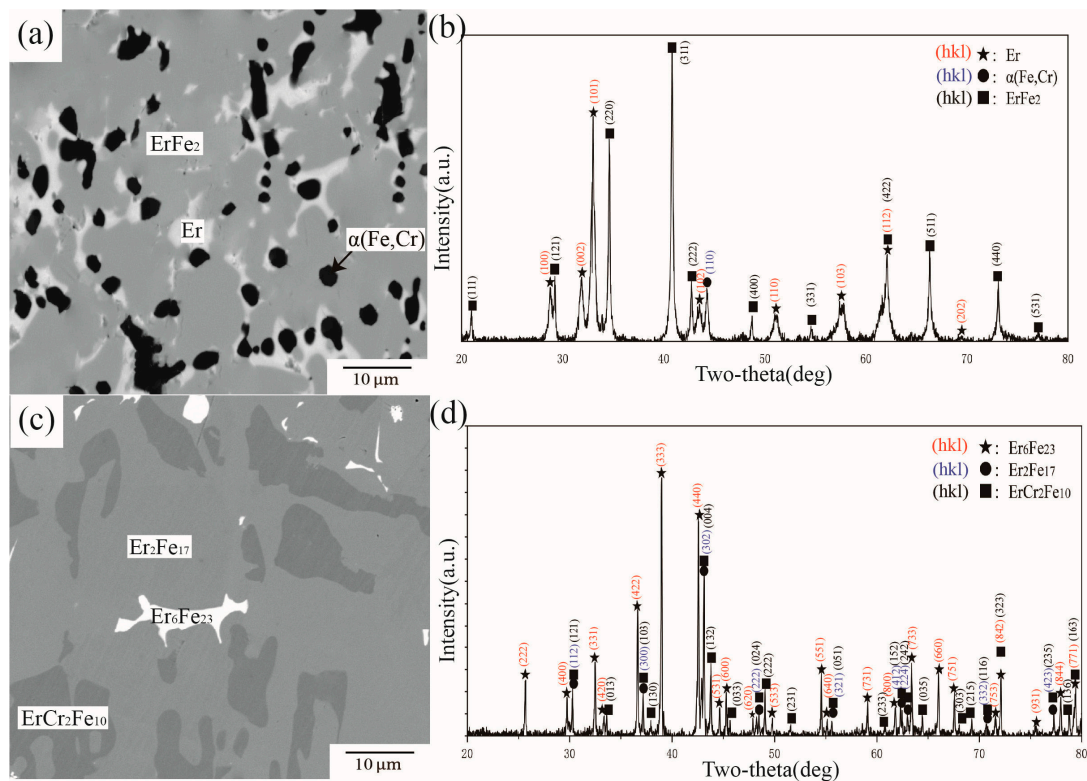

Figure 14. (**a**) BSE image of alloy C4, (**b**) XRD result of alloy C4, (**c**) BSE image of alloy C8, (**d**) XRD result of alloy C8.

There are three obvious contrasts in the BSE images of alloy samples C9 and C11, as shown in Figure 15a,c. By comparing standard PDF cards and the characteristic peaks in Figure 15b,d, C9 and C11 belong to three-phase equilibrium $ErFe_2$ + Er + $\alpha(Fe,Cr)$ and Er_2Fe_{17} + Er_6Fe_{23} + $ErCr_2Fe_{10}$, respectively. By analyzing WDS data obtained, the maximum solid solubilities of Cr in $ErFe_2$ and Er_2Fe_{17} were 7.50 at.% and 16.23 at.%, respectively. The solubility of Cr in Fe–Er binary compounds is significantly reduced compared with that at 1073 K and 1273 K.

5. Conclusions

In this work, the phase relationships of the Fe–Cr–Er ternary system at 1273 K, 1073 K, and 973 K results were systematically studied by combining data from WDS, XRD, and SEM measurements. There are nine single-phase regions, 16 two-phase regions, and eight three-phase regions at 973 K and 1073 K. At 1273 K, the σ phase disappeared, and liquid appeared. Phase equilibrium relationships are similar in the different isothermal sections studied in this work. Although the solid solubility of Fe–Er binary compounds is not completely consistent with the marginal binary phase diagram due to the influence of Cr, the phase relationship is basically similar. The maximum solid solubilities of Cr in $ErFe_2$, $ErFe_3$, Er_6Fe_{23}, and Er_2Fe_{17} were 15.19 at.%, 2.47 at.%, 18.67 at.%, and 18.89 at.% at 1273 K, respectively. These values reduced to 10.70 at.%, 1.81 at.%, 14.85 at.%, and 17.77 at.% at 1073 K and continued to decrease to 8.12 at.%, 1.79 at.%, 14.33 at.%, and 16.23 at.% at 973 K, respectively. $ErCr_2Fe_{10}$ existed in all three isothermal sections, from which it can be determined that it forms a stable ternary compound from 973 K to 1273 K. At 1273 K, Cr had the strongest solubility in $ErCr_2Fe_{10}$, and the solid solubility ranged from Fe10.2Cr1.8Er to Fe7.5Cr4.5Er. Accurate determination of solubility range can help to analyze the existence

and movement behavior of elements in phases. These isothermal sections at 1273 K, 1073 K, and 973 K provide the possibility of obtaining a thermodynamic description using the CALPHAD (CALculation of PHAse Diagrams) method. Thermodynamic optimization can calculate the phase relationship of the system at any temperature, combine the physical, chemical, and mechanical properties of the phase, and guide alloy composition design in actual production to obtain a desired material.
