Abstract: Insulin affects wound healing by reducing inflammation, regulating oxidative reactions, and increasing collagen deposition. Despite the many benefits of insulin, there is still no topical product for insulin delivery through the skin on the market. The aim of this study was to review the literature on the development of a hydrogel formulation of insulin to promote wound healing. An analysis of papers published between 2000 and 2022 was carried out. Embase, Medline, PubMed, and Cochrane Library databases were used. Hydrogels may provide a starting point for developing new products or improving the efficacy of designed epidermal forms of insulin. The hydrogels used allow efficient delivery of the peptide into the wound environment.

Keywords: hydrogel; polymers; insulin; topical; diabetic ulcers; wound healing; chronic wounds

1. Introduction

Insulin (INS) is a peptide hormone that has many physiological functions and, in particular, is involved in the regulation of blood glucose levels. The presence of insulin receptors in the keratinocytes and fibroblasts of the epidermis was previously confirmed [1]. It was previously found to affect wound healing by reducing inflammation, regulating oxidative reactions, and increasing collagen deposition [2]. Topical application of insulin to skin wounds stimulates the migration and proliferation of fibroblasts and endothelial cells, as well as the production of extracellular matrix proteins. Furthermore, insulin stimulates the migration of keratinocytes in a dose-dependent manner by activating a transcription nuclear factor-kappa B (NF-κB) [3–6]. The hormone was previously found to promote the closure of wound edges by activating the ERK1/2 and PI3K signaling [7]. The effect of insulin on accelerated wound healing involves increased expression of the integrin receptors laminin (α3β1) in keratinocytes, as well as an increase in the levels of LN332 (Laminin 332) [6]. INS prevents cell apoptosis induced by inflammatory processes and promotes angiogenesis (development of new blood vessels) by stimulating the expression of VEGF through AKT signaling [8]. It regulates inflammatory responses in the wound by inducing advanced infiltration and resolution of macrophages [9]. In pre-clinical studies, topical administration of insulin as a solution or ointment was found to have no effect on blood glucose levels [10]. Figure 1 shows the therapeutic potential of insulin in the treatment of chronic and acute skin wounds [11–17].

Despite the many benefits of insulin for wound healing, no skin-based preparation of insulin is currently on the market. The problem is the lack of stability of this peptide in the wound bed. The presence of proteases in the wound environment deactivates the hormone.
Research efforts undertaken in recent years to develop a topical form of insulin focused on designing an effective carrier to improve the stability of the peptide drug.

An analysis of papers published between 2000 and 2022 was performed. Embase, Medline, PubMed, and Cochrane Library databases were used. The following keywords were used: hydrogel, polymers, insulin, topical, diabetic ulcers, wound healing, and chronic wounds. The search procedure was simplified using the “AND” operator. Conference abstracts and non-English language articles were omitted. In total, 12 publications met the search criteria.

**2. Materials and Methods**

An analysis of papers published between 2000 and 2022 was performed. Embase, Medline, PubMed, and Cochrane Library databases were used. The following keywords were used: hydrogel, polymers, insulin, topical, diabetic ulcers, wound healing, and chronic wounds. The search procedure was simplified using the “AND” operator. Conference abstracts and non-English language articles were omitted. In total, 12 publications met the search criteria.

**3. Results and Discussion**

Wound healing is a complex and dynamic biological process that involves the repair of damaged cellular and tissue structures. It proceeds through several phases, such as hemostasis, inflammation, angiogenesis, growth, re-epithelialisation, and re-modeling [18]. The duration of each phase depends on the type of wound; the microbiological, immunological, and physiological factors; and the treatment used [19]. Currently, many pre-clinical and clinical studies are directed toward developing therapies that accelerate wound healing. Recently, a number of studies were published confirming the efficacy of insulin in the treatment of chronic wounds, a few of which involve the design of polymeric hydrogels for topical application. Hydrogels can provide a starting point for developing new products or improving the efficacy of engineered topical forms of insulin. They exhibit a number of favorable characteristics, such as low cost, ease of preparation, ease of application, an ability to retain significant amounts of water or biological fluids in the matrix, biocompatibility, an ability to mimic the natural physical properties of tissues, an ability to accumulate nano- and micro-forms of the drug in their structure, and efficient release of the active substance [20]. The use of hydrogels as an insulin carrier provides a moist environment in the wound area, protection against infection, and tissue regeneration [21]. Table 1 includes research work on the development of a hydrogel preparation for insulin.

Abbreviations: NPs, nanoparticles; PVA, poly(vinyl alcohol); PLGA, poly(lactide-co-glycolide).

The hydrogels used are three-dimensionally crosslinked polymeric networks [29]. Of note is the type of polymers used, which included both natural and synthetic biomaterials. Natural polymers (including collagen, gelatin, silk, chitosan, cellulose, alginate, and hyaluronic acid) show the ability to mimic native tissue structure and function. They are biocompatible and rarely cause inflammatory reactions. Unfortunately, they are subject to enzymatic degradation and exhibit unsatisfactory mechanical properties. The most commonly used synthetic polymers, on the other hand, are poly(ethylene glycol) (PEG), poly (lactic acid) (PLA), and poly (lactide-co-glycolide) (PLGA). They can be chemically modified, affecting their crosslinking density, mechanical strength, and controlled degradation. However, they are characterized by low biodegradability and an increased risk of inflammation [30].

Poly(vinyl alcohol) (PVA) is a biocompatible synthetic polymer with a high content of hydroxyl functional groups. It is characterized by high strength and exhibits non-toxicity and biodegradability [29,31]. Cai et al. [22] used PVA (with the addition of glycerol, which is a hydrophilic plasticiser) as a matrix for insulin. They conducted their study in a rat model and confirmed prolonged insulin release from the carrier over 10 days. Abdelkader et al. [6] found that insulin-loaded PLGA NP (poly(lactide-co-glycolide nanoparticles) suspended in structured poly (vinyl alcohol)-borate hydrogel improved wound healing.

Chitosan is a β-1,4-polysaccharide of natural origin with valuable biological properties. The polymer is non-toxic and biodegradable, exhibits microbial inhibition (destabilising the outer membrane of gram-negative bacteria), and accelerates wound healing [30]. Dawood et al. [23] designed an insulin-loaded liposomal chitosan gel. The liposomal encapsulation of insulin gave INS high stability (6 months in an aqueous dispersion state at 4 °C), and the hormone was released over 24 h. Compared to the control group, the wound healed 16 times faster. Other authors confirmed that insulin-containing chitosan nanoparticles show the ability to stimulate inflammatory cell proliferation and angiogenesis, followed by wound maturation [26]. Zhu et al. [21] prepared gels based on oxidised hyaluronic acid and
succinyl chitosan for integration with insulin-loaded micelles. They conducted the study on rats with induced diabetes and confirmed the applicability of the developed material for wound healing. The technological procedure of combining two types of polymers enables greater mechanical stability of the obtained hydrogel and improves its mechanical properties [32].

Alginate is a biopolymer that is biocompatible and non-toxic. It demonstrates the ability to form hydrogels through interactions with calcium ions, etc. It minimises the risk of bacterial infection at the wound site [32]. Dhall et al. [13] confirmed that insulin in the PLGA-alginate matrix stimulates regenerative burn wound healing in a rat model. Insulin enhances re-epithelialisation via stimulating angiogenesis. Another hydrogel based on aloe vera shows antibacterial, anti-septic, and anti-inflammatory characteristics, as well as an ability to stimulate fibroblast proliferation and collagen synthesis [33]. Chakraborthy et al. [28] developed a gel formulation of aloe vera with insulin-loaded nanoemulsion. They tested the efficacy of the formulation in a diabetic rat model. The authors found an improvement in the skin histological architecture in a group containing rats with wounds on their backs. The results obtained confirm that aloe vera can be a competitive carrier for improving skin wound healing. In contrast, the hydrogel formulation based on insulin-conjugated keratin, which was proposed by Li et al. [24], promotes hemostasis and tissue regeneration.

Pluronic F127 (poloxamer) is an amphiphilic thermosensitive polymer of the copolymer group. Quitério et al. [1] developed insulin-loaded poly-DL-lactide/glycolide (PLGA) nanoparticles in a Pluronic F-127 ((polyethylene oxide-b-propylene oxide-b-ethylene oxide, POLX) gel. The authors confirmed the stability of insulin after encapsulation and the release of the hormone from NPs. The developed formulation with insulin reduced the healing time of burn wounds.

Carbomer (trade name: Carbopol) is a polymer available in several different grades, which differ in terms of the percentage content of crosslinking agents. It allows the preparation of stable hydrogels in acidic and basic environments [34]. It has mucoadhesive properties. Increasingly, this polymer is being used to develop controlled drug delivery systems [35,36]. Kaur et al. [25] used Carbopol-980 as a carrier for insulin-loaded silver nanoparticles (AgNPs). The developed formulation showed significant therapeutic activity in vitro and in vivo. It resulted in faster wound healing in normal and diabetic rats. The mechanism of action involved promoting wound remodeling by regulating the relationship between positive inflammatory factors (IL-6, TNFα) and negative inflammatory factors (IL-10). High efficacy in developing a hydrogel formulation with insulin was also confirmed for Carbopol Ultrez 10 and Carbopol Ultrez 30 [27]. A study by Besson et al. [11] also confirmed the effectiveness of Carbopol 940 as a carrier of complexed insulin with 2-hydroxypropyl-β-cyclodextrin (HPβCD). Slow release of INS from the complex modulated the re-epithelialisation process by stimulating cell proliferation and migration of keratinocytes.

4. Conclusions

The results of the study confirm that topical administration of insulin improves wound healing without significantly affecting the occurrence of side effects. The use of hydrogels allows efficient delivery of the peptide into the wound environment. We believe that work on insulin formulations should continue, as this will allow the mechanism of action of this hormone on wounds to be explored and an effective formulation to be developed for clinical use. Hydrogels are a promising direction for the development of an insulin carrier. We would like the present work to inspire further research investigations.
