**Abstract:** Gross Primary Productivity (GPP) for cropland is often estimated using a fixed value for maximum light use efficiency ( $LUE_{max}$ ) which is reduced to light use efficiency (LUE) by environmental stress scalars. This may not reflect variation in LUE within a crop season, and environmental stress scalars developed for ecosystem scale modelling may not apply linearly to croplands. We predicted LUE on several vegetation indices, crop type, and agroclimatic predictors using supervised random forest regression with training data from flux towers. Using a fixed  $LUE_{max}$  and environmental stress scalars produced an overestimation of GPP with a root mean square error (RMSE) of 6.26 gC/m<sup>2</sup>/day, while using predicted LUE from random forest regression produced RMSEs of 0.099 and 0.404 gC/m<sup>2</sup>/day for models with and without crop type as a predictor, respectively. Prediction uncertainty was greater for the model without crop type. These results show that LUE varies between crop type, is dynamic within a crop season, and LUE models that reflect this are able to produce much more accurate estimates of GPP over cropland than using fixed  $LUE_{max}$  with stress scalars. Therefore, we suggest a paradigm shift from setting the LUE variable in cropland productivity models based on environmental stress to focusing more on the variation of LUE within a crop season.

## 1. Introduction

Gross Primary Productivity (GPP) and Net Primary Productivity (NPP) underpin many global estimates of crop production with remote sensing. They express the rate of carbon fixation by plants, from which measures such as cumulative biomass production and yield can be derived. For example, several global crop yield maps are now available which estimate grain yield from GPP or NPP [1,2]. Furthermore, there is increasing use of remote sensing methods to monitor carbon dynamics over agricultural lands [3,4]. Therefore, it is important that the accuracy of productivity estimation methods is continually monitored and improved.

Remote sensing estimates of productivity at a point in time are generally based on a Production Efficiency Model since Monteith [5,6] defined productivity as a function of incoming solar radiation and light use efficiency (LUE) (Equation (1)):

$$GPP = fPAR \times PAR \times LUE, \quad (1)$$

where  $GPP$  is a function of photosynthetically active radiation ( $PAR$ ), the fraction of this which is absorbed by plants ( $fPAR$ ), and  $LUE$ . This can be applied to either  $GPP$  or  $NPP$ , and  $LUE$  values may refer to either measure [7–10]. We focus on  $GPP$  in this paper as it forms the basis of several current cropland products [11–13].

Early efforts to optimise Production Efficiency Model parameters focused on  $fPAR$ , and attention has now turned to the  $LUE$  parameter, which has been recognised as a

critical component of the error budget in remote sensing GPP models [14–16]. Various approaches to setting the LUE parameter exist, which include assuming a globally fixed value, assuming a fixed value for each functional type of vegetation (C3 grass, C4 grass, and trees), or varying LUE dynamically with vegetation type and environmental stressors [8,14]. The latter approach, known as the Carnegie–Ames–Stanford Approach (CASA) has been widely applied to both NPP and GPP estimation for field crops [17,18] (Equation (2)):

$$GPP_{CASA} = fPAR \times PAR \times LUE_{max} \times TS \times VS \times SMS, \quad (2)$$

where maximum LUE ( $LUE_{max}$ ) is reduced below its potential by temperature stress ( $TS$ ), vapor stress ( $VS$ ), and soil moisture stress ( $SMS$ ) scalars to give  $LUE_{CASA}$ . This is a simple yet effective means of capturing environmental variation in LUE [8]. Alternatively, Donohue et al. [14] varied LUE based on the proportion of diffuse radiation which met or outperformed the stress scalar approach for accurate GPP estimation at a continental scale. However, each method relies on an accurate starting value for  $LUE_{max}$ . Lobell et al. [8] recognised that LUE, and thereby  $LUE_{max}$ , could be predicted based on relationships with satellite-derived vegetation indices [19,20]. For example, canopy greenness, as a proxy for crop maturity and stress, such as nutrient deficiency, may be useful predictors of LUE [21,22]. We sought to combine vegetation indices with crop type and agroclimatic information to test whether a machine learning method could accurately predict cropland LUE.

A contrasting approach for setting LUE for agricultural applications is setting a fixed  $LUE_{max}$  based on information such as crop type, and sometimes soil fertility and fertiliser regimes [8]. For example, the Global Yield Mapper in Google Earth Engine (GYMEE) notes uncertainty in defining  $LUE_{max}$  for crop type and applies 2.5 gC/MJ/day for C3 crops and 3.5 gC/MJ/day for C4 crops [1]. Similarly, the Python implementation for the Surface Energy Balance Algorithm (PySEBAL) documentation for estimating crop biomass production and evapotranspiration recommends  $LUE_{max}$  values of 2.5 gC/MJ/day and 4.5 gC/MJ/day for C3 and C4 crops, respectively [12,13,23].

However, fixed  $LUE_{max}$  measured at the field or plant levels may be much greater than  $LUE_{max}$  applicable to remote sensing scales. Calculating in situ  $LUE_{max}$  from flux tower GPP measurements has revealed overestimation of  $LUE_{max}$  for croplands and therefore overestimation of remotely sensed GPP. For example, Wang et al. [9] calculated  $LUE_{max}$  values ranging from approximately 2.3 to 3.7 gC/MJ/day for maize and 1.4 gC/MJ/day for wheat from flux tower sites. Similarly, Xin et al. [24] calculated mean values of 2.78 and 1.64 gC/MJ/day for maize and soybean, respectively. These values are generally greater than estimates of  $LUE_{max}$  for global or continental products such as the Moderate-Resolution Imaging Spectroradiometer (MODIS) GPP, but less than values generated in field experiments. This has led to an underestimation of cropland GPP in continental products and overestimation of GPP when fixed  $LUE_{max}$  values are used in cropland-specific applications [7,24,25].

In addition to overestimation of  $LUE_{max}$ , there are two main reasons why CASA with fixed  $LUE_{max}$  may not adequately quantify LUE for cropland. The first is that neither a fixed coefficient for  $LUE_{max}$  nor the stress scalars (Equation (2)) account for within-season variation in LUE, which has been demonstrated for a range of field crops. For example, Gitelson and Gamon [15] show that LUE varied within maize- and soybean-growing seasons, both before ( $LUE_{inc}$ ) and after ( $LUE_{total}$ , referred to as LUE in this paper) fPAR was accounted for, and Lecoeur and Ney [26] show a similar temporal pattern for field peas. Gitelson et al. [16] recognised the two to three-fold variation in LUE within growing seasons for maize and soybean meant this source of variation “should be accounted for in LUE models”.

The second reason that CASA may not apply well to croplands is that stress scalars may be less relevant in managed environments, especially irrigated croplands, than in other vegetated land types. Lobell et al. [8] found that omitting stress scalars from CASA (Equation (2), adapted for NPP) improved NPP estimation accuracy for irrigated and

temperature-resistant crops. Therefore, an alternative approach to setting the LUE variable for cropland productivity estimations based primarily on within-season variation in crop growth may be superior to the CASA method.

In this paper, we investigate whether a non-parametric, machine learning, predictive model for LUE based on satellite-derived vegetation indices and agroclimatic variables can give more accurate GPP predictions for cropland than CASA. This approach differs from previous studies in its non-parametric approach, and specificity and scalability to croplands. Relationships between vegetation indices and both LUE and GPP for cropland have been investigated by Peng et al. [27], and Peng and Gitelson [28], though these have generally focused on parametric modelling approaches relating GPP or LUE to individual indices. Non-parametric random forest approaches have been applied to prediction of LUE at the global scale by Wei et al. [29] based predominantly on meteorological and land use/land cover predictors. Our approach is unique in its use of both agroclimatic and vegetation indices as predictor variables that have previously been investigated separately, its specificity to cropland and crop type, and its scalability due to reliance on globally-available Landsat and climate data.

To this end, flux tower data were used to derive  $GPP_{in situ}$  and  $LUE_{in situ}$ , and demonstrate how these varied within a crop season and between crop type. The in situ values were compared with satellite-based estimates of  $LUE_{CASA}$ , and  $GPP_{CASA}$ .  $LUE_{in situ}$  was also used to train a machine learning model with satellite data, crop type, and agroclimatic variables as predictors. The importance and dependence of each predictor in the model were evaluated to assess which variables best predicted LUE, and to understand how vegetation indices and agroclimatic information relate to LUE within a crop season. Finally, the accuracy of  $GPP_{CASA}$  estimates was compared with the accuracy of predicted GPP ( $\hat{GPP}$ ) using predicted LUE ( $\hat{LUE}_{RF}$ ) from the random forest regression model.

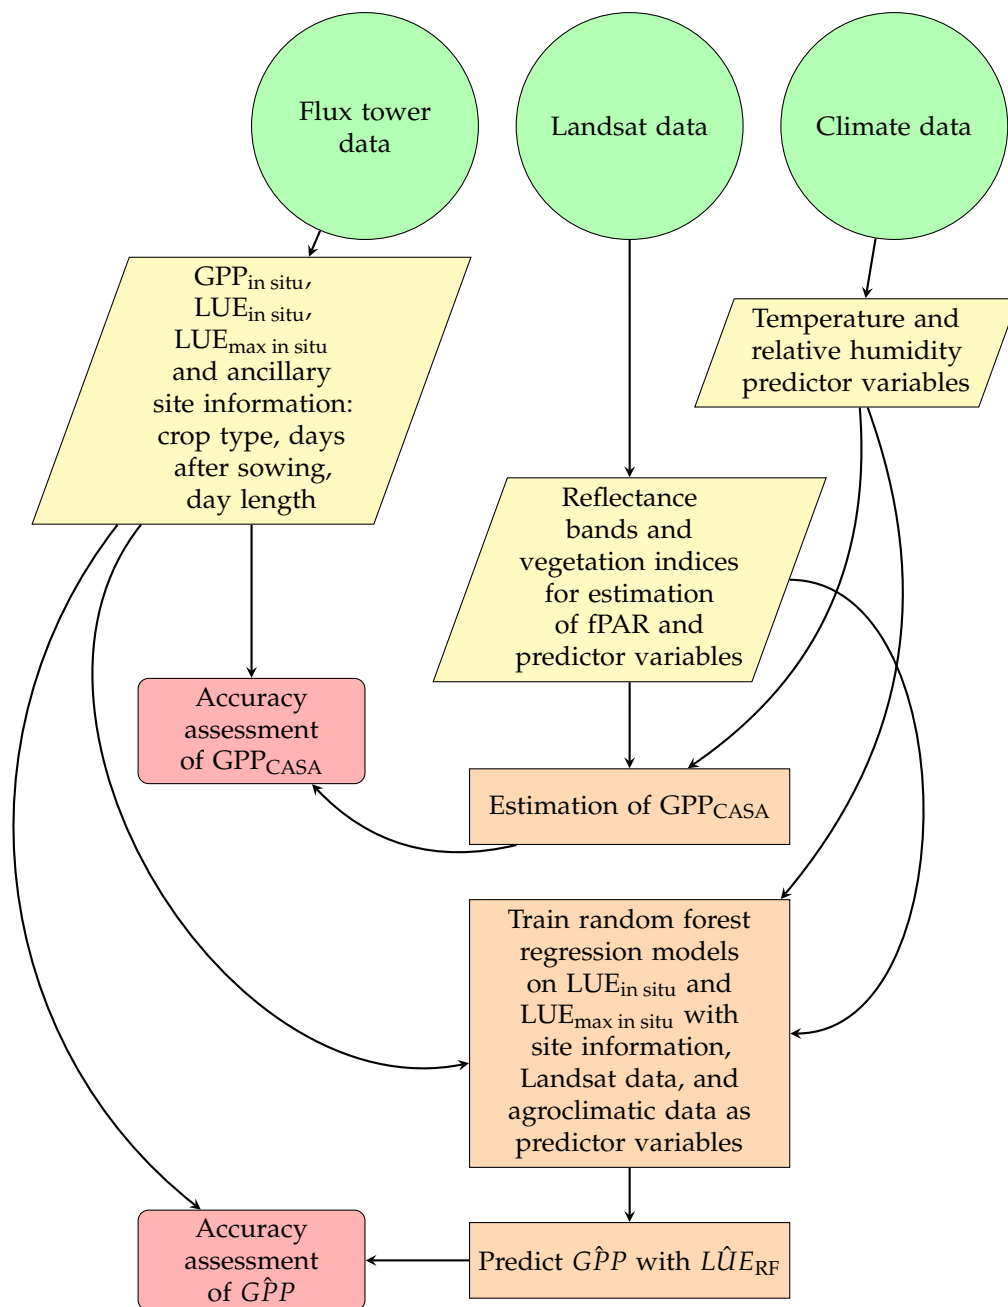

## 2. Materials and Methods

### 2.1. Overview of Methodology

We used flux tower data for  $GPP_{in situ}$  to assess the accuracy of remotely sensed GPP. From this,  $LUE_{in situ}$  was also derived, which was then used as training data for the predictive model. This process is summarised in Figure 1 and details of  $LUE_{in situ}$  and  $LUE_{max in situ}$  estimation are provided in the following sections.

### 2.2. Flux Tower Data

Flux tower sites corresponding to cropland were identified within the FLUXNET database [30]. From these, sites with known crop species were selected so accuracy could be assessed between crop functional type (C3 and C4) and crop species. Table 1 shows the FLUXNET tower sites used. Data were downloaded from the FLUXNET database in daily format. The number of observations was determined by the number of days during active years where a clear Landsat 7 or 8 image was available over the site, and crop growth was occurring, which was defined as GPP being  $\geq 0.1 \text{ gC/m}^2$ .

**Figure 1.** Flowchart of methodology showing data sources (circles), data items (trapezoids), algorithms or estimations (rectangles), and accuracy assessments of GPP estimations (rounded rectangles).

### 2.3. Satellite and Climate Data

At present, Landsat mission satellites offer useful spatial resolution and historical temporal coverage for cropland applications. Several software applications readily support GPP calculations from Landsat images. We used the Python script PySEBAL because it produces a biomass estimate based on GPP from the CASA equation, and also gives outputs required to calculate stress scalars, such as transpiration and evaporation [12,23].

**Table 1.** Flux tower sites used to derive  $GPP_{in situ}$  and  $LUE_{in situ}$ .

Site Name	Site Code	Years Active	Crop Species	Observations
Cheorwon Rice paddy	KR-CRK [31]	2015–2018	Rice	15
Philippines Rice Institute flooded	PH-RiF [32]	2012–2014	Rice	19
Humnoke Farm Rice Field A	US-HRA [33]	2017	Rice	4
Humnoke Farm Rice Field C	US-HRC [34]	2017	Rice	4
Mead-irrigated continuous maize site	US-Ne1 [35]	2001–2013	Maize	47
Mead-irrigated maize–soybean rotation site	US-Ne2 [36]	2001–2013	Maize (odd years), soybean (even years)	33
Mead-rainfed maize–soybean rotation site	US-Ne3 [37]	2001–2013	Maize (odd years), soybean (even years)	46

Both Landsat-7 and Landsat-8 imagery were used to cover the epoch from 2001 to 2018 (Table 1). Collection 1 Level-1 images with less than 20% cloud cover were downloaded from the USGS Earth Explorer website. Landsat band digital numbers were converted to top of atmosphere reflectance values using the scaling coefficients in metadata files. Landsat-7 imagery must be spatially gapfilled to correct the scan line corrector (SLC) failure. Jaafar et al. [38] reported more consistent outputs from PySEBAL when Landsat-7 bands were gapfilled using the ‘focal’ function from the R package ‘raster’ [39]. Therefore, a  $3 \times 3$  moving window was applied to Landsat-7 bands using the ‘focal’ function to fill pixels identified as having null values in R version 4.1.1 [40].

PySEBAL requires 24 average and instantaneous shortwave radiation, wind speed, air temperature, air pressure and relative humidity as inputs. These were derived from the National Aeronautics and Space Administration’s Global Land data assimilation system (GLDAS) [41]. Climate observations closest in time to the Landsat overpass time were used as the instantaneous values while means were calculated across the eight observations for each day to form 24 h average values [11,12].

To complete the required inputs for PySEBAL, a digital elevation model (DEM) was acquired from the Shuttle Radar Topography Mission (SRTM) [42] and soil physical properties were derived from the HiHydroSoil dataset [43].

## 2.4. Remote Sensing Estimation of Gross Primary Productivity and Light Use Efficiency

### 2.4.1. Analysis Boundary

All remotely sensed measures were masked to an approximate cropland ecosystem boundary which was defined as a  $10 \times 10$  matrix of Landsat pixels surrounding the flux tower, giving an area of approximately  $300 \text{ m} \times 300 \text{ m}$ . This area was chosen across sites because flux tower height was generally set at a level which best captured the immediate field and eliminated surrounding landscapes [44], and this area generally fell within the target fields while enabling consistent spatial sampling from each site. This area was also consistent with former studies on flux tower sites which have used both Landsat and MODIS resolutions and therefore enhanced comparability of error across approaches [22,24,27,45]. The mean of values across the  $10 \times 10$  matrix were taken for all remotely sensed variables to generate the final dataset with the number of observations shown in Table 1.

More recent flux tower initiatives have captured meteorological variables which enable calculation of flux footprints for use in future studies [46,47].

### 2.4.2. Remotely Sensed Gross Primary Productivity

Initial estimates of  $GPP_{CASA}$  were used to calculate a baseline error against  $GPP_{in situ}$ ; this is the foremost accuracy assessment in Figure 1. The output map of biomass production from PySEBAL expresses GPP in  $\text{kg/ha/day}$  as calculated in Equation (2) [11,12,23].

PySEBAL was run with the recommended  $LUE_{max}$  values of 2.5 gC/MJ/day for C3 crops (rice, soy) and 4.5 gC/MJ/day for C4 crops (maize). This output map was multiplied by 0.1 to convert from kg/ha to gC/m<sup>2</sup>.

#### 2.4.3. Calculation of Light Use Efficiency and Stress Scalars

$LUE_{in situ}$  and  $LUE_{max in situ}$  corresponding to Landsat overpass dates were calculated by inversion of the GPP (Equation (1)) and CASA equations (Equation (2)) [8,10]. Daily  $GPP_{in situ}$  and incoming shortwave radiation were available from FLUXNET datasets for each site. Other parameters were kept consistent with the PySEBAL script [12,23] due to its specificity to cropland and its similarity to other GPP estimates for cropland including GYMEE [1]. The variable,  $fPAR$ , was calculated on Landsat images as:

$$fPAR = -0.161 + 1.257 \times NDVI, \quad (3)$$

conditional on the Normalised Difference Vegetation Index ( $NDVI$ ) being  $\geq 0.125$ , below which  $fPAR$  was set as 0. This definition of  $fPAR$  has been widely applied to cropland applications since Bastiaannssen and Ali [48] aggregated coefficient and intercept values from several cropland experiments, including the work of Daughtry et al. [49] on maize and soybean.

$PAR$  was calculated as:

$$PAR = Rs \times 0.48 \times 0.0864, \quad (4)$$

where  $PAR$  is 48% of incoming shortwave radiation ( $Rs$ ) [48] and 0.0864 converts W/m<sup>2</sup> to MJ/m<sup>2</sup>/day.

Temperature stress ( $TS$ ) was calculated based on Stewart [50,51] and Jarvis [52] as:

$$TS = \frac{(T - T_l) \times (T_h - T)^{Jc}}{(K_t - T_l) \times (T_h - K_t)^{Jc}} \quad (5)$$

where  $T$  is the average daily temperature and  $Jc$  is the Jarvis coefficient, calculated as:

$$Jc = \frac{T_h - K_t}{K_t - T_l}, \quad (6)$$

where  $Th$ ,  $Kt$ , and  $Tl$  are the upper limit, optimum value, and lower limit of temperatures (°C) for stomatal conductance, respectively. These constants were made consistent with the PySEBAL script [12,23] Constants used in Equations (5) and (6) are presented in Table 2.

**Table 2.** Constant values used for calculation of temperature stress in the estimation of  $GPP_{CASA}$ .

Constant	Definition	Source
$Tl$	0 °C	[53,54]
$Kt$	23 °C	[53,54]
$Th$	35 °C	[53,54]

Vapor stress ( $VS$ ) was calculated based on Oren et al. [55], and Fuchs and Stanghellini [56], as:

$$VS = 0.88 - 0.183 \times \log(E_{sat} - E_{act}), \quad (7)$$

where  $E_{sat}$  and  $E_{act}$  are the saturated and actual vapor pressure (kPa), respectively.

Soil moisture stress ( $SMS$ ) was calculated as the ratio of actual ( $T_{act}$ ) to potential ( $T_{pot}$ ) 24 h transpiration [57]:

$$SMS = T_{act} / T_{pot}, \quad (8)$$

where  $T_{act}$  and  $T_{pot}$  were taken from PySEBAL output maps and masked according to Section 2.4.1.

## 2.5. Modelling Light Use Efficiency

### 2.5.1. Predictor Variables

Several satellite bands, vegetation indices, and agroclimatic variables were used as predictors for LUE. Although vegetation indices vary with crop maturity [16], we included both days after sowing (DAS) and day length as predictor variables to capture potential within-season variation in LUE. Using DAS as a predictor overcame the limitation of using day of year which may be site, rather than crop type, specific. The inclusion of these predictors also enabled the relative importance of seasonality and vegetation indices to be investigated.

Satellite-derived data were masked according to the analysis boundary as per Section 2.4.1. The details of each predictor variable used in the random forest regression models are summarised in Table 3.

**Table 3.** Definition of predictor variables used to train predictive models for light use efficiency.

Group	Variable	Definition	Source
Satellite bands	Blue	Landsat-7: 0.45–0.52 $\mu\text{m}$ Landsat-8 0.45–0.51 $\mu\text{m}$	[58]
	Green	Landsat-7: 0.52–0.60 $\mu\text{m}$ Landsat-8 0.53–0.59 $\mu\text{m}$	[58]
	Red	Landsat-7: 0.63–0.69 $\mu\text{m}$ Landsat-8 0.64–0.67 $\mu\text{m}$	[58]
	Near Infrared (NIR)	Landsat-7: 0.77–0.90 $\mu\text{m}$ Landsat-8 0.85–0.88 $\mu\text{m}$	[58]

### 2.5.2. Random Forest for Light Use Efficiency

Random forests [66] is a machine learning algorithm which was used to develop a predictive model for LUE using the randomForest package in R [67]. The method uses an ensemble approach to build a large number of regression trees on bootstrap samples (typically 500) of the original dataset with varying inputs. Predictions from regression trees are aggregated to estimate  $LUE_{RF}$  and uncertainties can be quantified through the assessment of quantiles from the bootstrap distribution of outputs.

Three predictive models for LUE were trained and evaluated: one trained on  $LUE_{in situ}$  with all 17 variables in Table 3 and one without crop type, as this may not always be known to users. A third model was also trained on  $LUE_{max in situ}$  using all 17 predictors to determine whether this parameter could be accurately modelled. Variable importance was extracted from the model and expressed as the percentage increase in mean squared error (MSE). The out-of-bag (OOB) predictions for  $LUE_{RF}$  were used to calculate GPP using

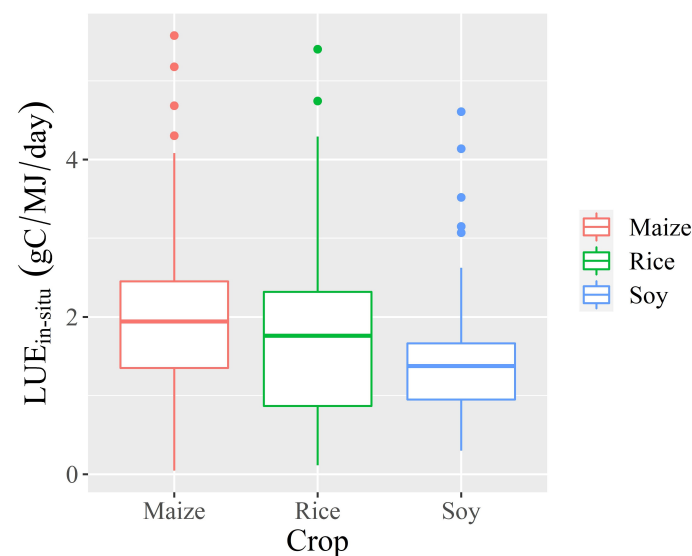

Equation (1). We refer to this as  $\hat{GPP}$ . An OOB prediction for an observation,  $LUE_i$ , is based on trees which do not use the in situ value of  $LUE_i$  in the bootstrapped training sample. Evaluations based on OOB predictions are therefore not prone to overfitting and are an alternative to traditional cross validation. The accuracy of  $\hat{GPP}$  against  $GPP_{in\ situ}$  was evaluated using the root mean square error (RMSE) and mean error (ME). These formed the latter accuracy assessment shown in Figure 1, which was compared with the accuracy for  $GPP_{CASA}$  (Equation (2)), the foremost accuracy assessment in Figure 1. Prediction uncertainty was calculated for each random forest model. This was presented as the standard error on the OOB prediction and calculated using the randomForestCI package [68].

### 3. Results

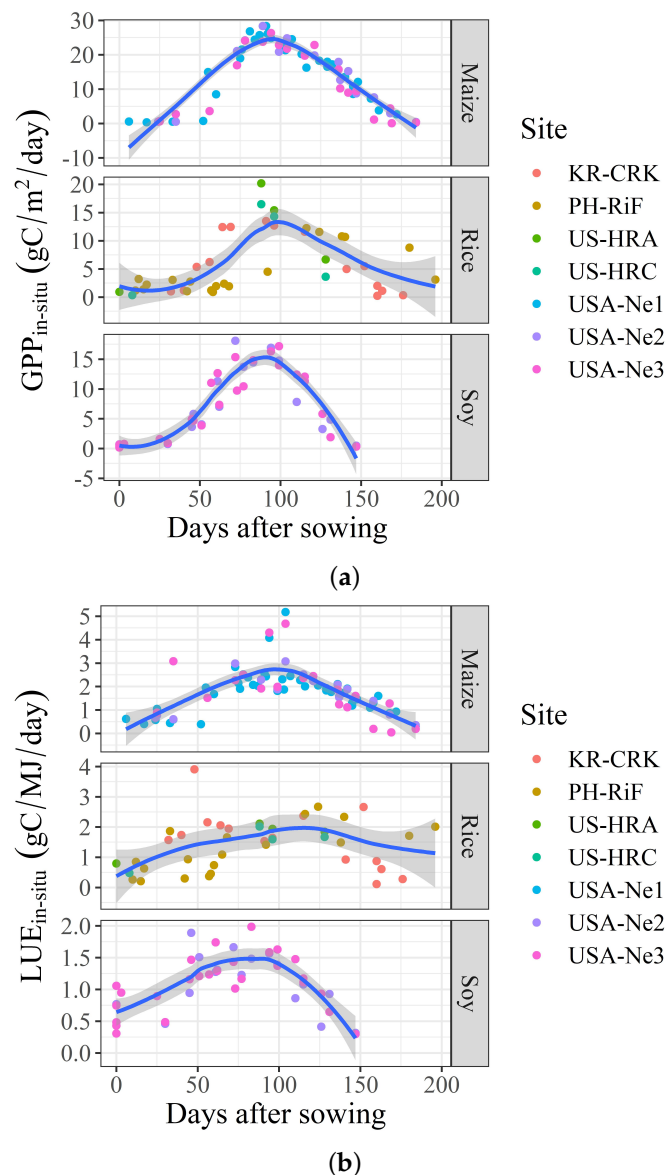

#### 3.1. In Situ Light Use Efficiency

$LUE_{in\ situ}$  was mostly distributed between 1 and 4 gC/MJ/day (Figure 2). Maize gave the highest median, and each median was below 2 gC/MJ/day.

The temporal pattern of  $LUE_{in\ situ}$  generally reflected the pattern in  $GPP_{in\ situ}$ . Both  $GPP_{in\ situ}$  and  $LUE_{in\ situ}$  rose to reach a mid-season maximum before declining, with the rate and timing of increase and decline varying between crop type (Figure 3). However, the pattern in  $GPP_{in\ situ}$  initially increased at an increasing rate, showing a sigmoidal plant growth curve, while  $LUE_{in\ situ}$  tended to show a more constant rate of increase. This was particularly evident in the locally fitted polynomial curves for soybean (Figure 3).

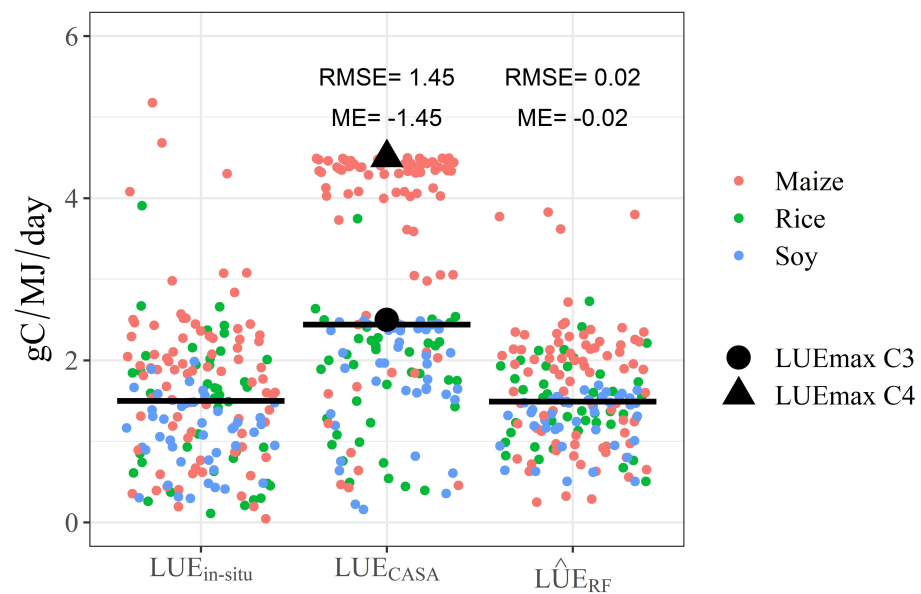

**Figure 2.** Distribution of in situ light use efficiency values derived from flux tower sites for maize, rice, and soy crops [11].

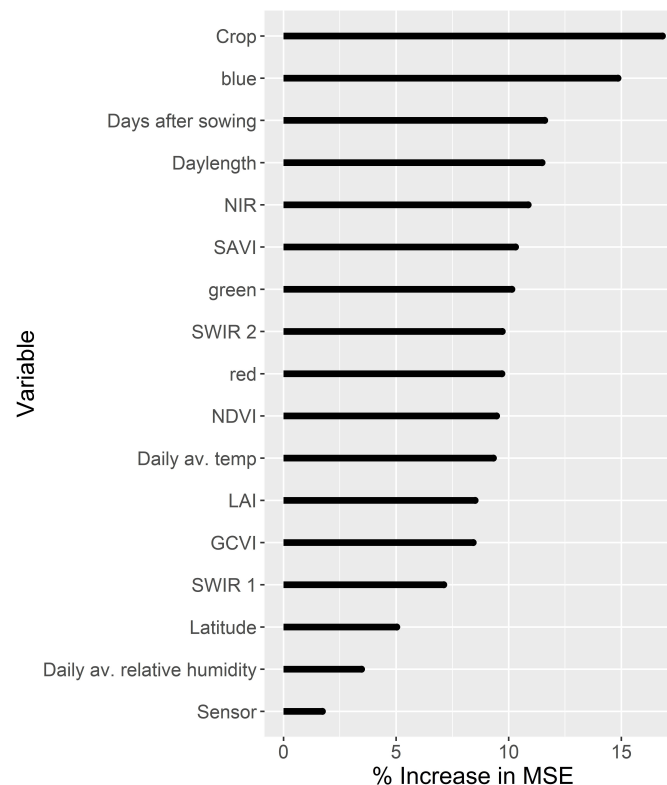

**Figure 3.** Figures showing (a) in situ Gross Primary Productivity (GPP) and (b) light use efficiency (LUE) aggregated by crop type and over crop seasons by day after sowing. Colours denote codes for the FLUXNET flux tower sites shown in Table 1. Plotted lines were fitted with a local polynomial regression and ribbons show the 95% confidence interval.

### 3.2. Prediction of Light Use Efficiency

The model which included crop type produced a higher  $R^2$  and lower mean of squared residuals (Table 4), indicating that crop type is an important predictor of LUE. This was reflected in the variable importance results (Figure 4). However, the OOB predictions for  $LUE_{max}$  from random forest models did not explain much variation in  $LUE_{max}$  in situ (Table 4). Additionally, Figure 5 shows that the stress scalars in the CASA Equation (2) do not sufficiently downscale the fixed  $LUE_{max}$  values to match  $LUE_{in\ situ}$ , especially for maize. The negative mean error indicates that  $LUE_{CASA}$  is an overestimate of  $LUE_{in\ situ}$ .  $\hat{L}UE_{RF}$  from Model 1 (Table 4) shows a much closer distribution to that of  $LUE_{in\ situ}$ . For this reason, only Models 1 and 2, which give  $\hat{L}UE_{RF}$ , not  $LUE_{max}$ , were chosen for further evaluation.

**Figure 4.** In situ light use efficiency ( $LUE_{in\ situ}$ ) values compared with LUE reduced below its potential by stress scalars as per Equation (2) ( $LUE_{CASA}$ ) and LUE predicted from a random forest model with satellite-derived and agroclimatic predictors ( $\hat{LUE}_{RF}$ ) in Table 3. Median is shown with a horizontal line, and the fixed maximum light use efficiency ( $LUE_{max}$ ) for C3 and C4 crops are shown with points.

**Figure 5.** Variable importance plot for the random forest regression model using all predictors shown in Table 3, expressed as percentage increase in mean square error.

Crop type was the most important predictor in Model 1 (Figure 5), reflecting variation in  $LUE_{in\ situ}$  between crops shown in Figure 2. Thereafter, the agroclimatic variables—day length, DAS, and temperature—were relatively important predictors. Vegetation indices

were of similar importance. Satellite bands were scattered amongst other predictors in terms of importance, and relative humidity was relatively unimportant.

Partial dependence plots (Figure 6) from random forest Model 1 show that LAI values less than approximately 2 reduced  $\hat{LUE}_{RF}$ . Higher SAVI and NDVI were associated with greater  $\hat{LUE}_{RF}$ , while GCVI between approximately  $-0.5$  and  $1$  reduced predicted values. Partial dependence on DAS reflected temporal patterns in GPP and LUE shown in Figure 3. Greater day length was associated with higher  $\hat{LUE}_{RF}$ , as was average temperature, although values greater than approximately  $25^{\circ}\text{C}$  reduced predictions.

**Figure 6.** Partial dependence of light use efficiency predictions on (a) vegetation index and (b) agroclimatic predictors in the random forest regression model fit with all variables in Table 3 as predictors.

**Table 4.** Performance of random forest prediction models for light use efficiency (LUE) (Models 1 and 2) and  $LUE_{max}$  (Model 3) expressed as percentage of variation in  $LUE_{in situ}$  or  $LUE_{max}$  in situ explained by variation in out-of-bag predictions ( $R^2$ ) for LUE/ $LUE_{max}$  and mean of squared residuals.

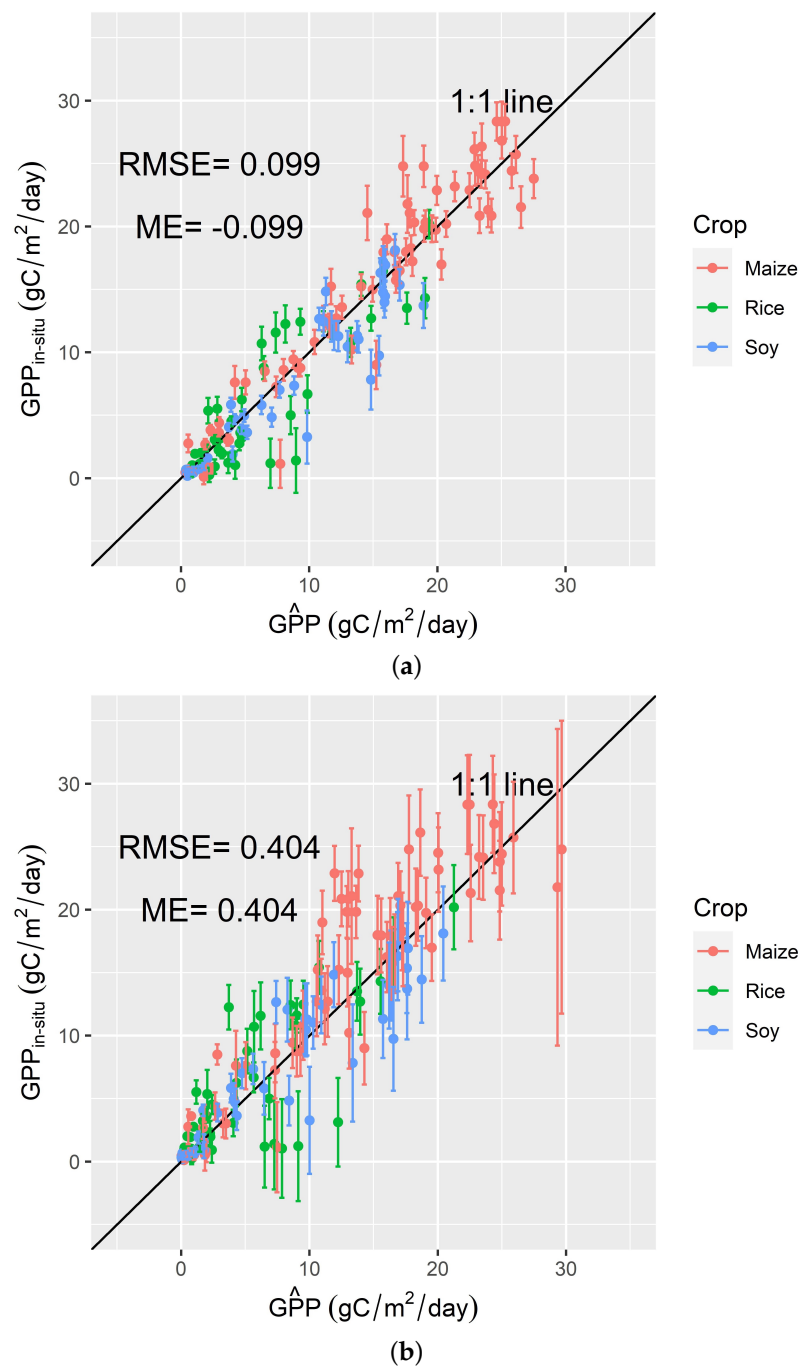

Measure	Model 1: All Predictors in Table 3	Model 2: No Crop Type Predictor	Model 3: All Predictors in Table 3, $LUE_{max}$ as Response
$R^2$	62.94%	58.30%	14.19%
Mean of squared residuals	0.28	0.32	0.87

### 3.3. Estimation of Gross Primary Productivity

CASA led to overestimation of GPP, as indicated by the negative ME, especially for maize (Figure 7). Estimating GPP with  $LUE_{RF}$  improved accuracy and reduced the RMSE between  $GPP_{in situ}$  and  $\hat{GPP}$  (Figure 8). Prediction uncertainty was greater and estimate accuracy was lower in the model that did not include crop type as a predictor (Figure 8).

**Figure 7.** Predicted Gross Primary Productivity ( $\hat{GPP}$ ) with fixed maximum light use efficiency values against  $GPP_{in situ}$  from flux tower sites in Table 1. Root mean square error (RMSE) and mean error (ME) between observed and predicted observations are shown.

**Figure 8.** Predicted Gross Primary Productivity ( $\hat{GPP}$ ) with predicted light use efficiency ( $L\hat{U}E_{RF}$ ) values from the model with (a) all predictor variables in Table 3 against  $GPP_{in-situ}$  from flux tower sites in Table 1, and (b) without crop type as a predictor. Root mean square error (RMSE) and mean error (ME) between observed and predicted observations are shown and the standard error on out-of-bag prediction is denoted by error bars.

#### 4. Discussion

$L\hat{U}E_{RF}$  from a machine learning model produced more accurate estimates of  $\hat{GPP}$  than  $GPP_{CASA}$  estimated with a fixed  $LUE_{max}$  and stress scalars, as shown in Figure 8. This was because CASA gave grossly overestimated GPP estimates (Figure 7) due to overestimation of  $LUE_{max}$  and insufficient downscaling from the stress scalars (Figure 4). These findings are consistent with Cheng et al. [25] who, using some of the flux tower sites in Table 1, found that CASA overestimated GPP by a RMSE of approximately  $6 gC/m^2/day$ , while the

MODIS MOD17 GPP product underestimated cropland GPP by a RMSE of approximately  $12 \text{ gC/m}^2/\text{day}$ . This means that using crop-specific  $\text{LUE}_{\text{max}}$  values in CASA is likely to produce more accurate estimates of GPP than continental GPP products over cropland, and that accuracy can be further improved by varying LUE using a predictive model.

Furthermore, prediction of  $\hat{\text{LUE}}_{\text{RF}}$  on a combination of agroclimatic and vegetation index predictors for calculation of  $\hat{\text{GPP}}$  gave more accurate estimates than other approaches applied to these flux tower sites. Peng and Gitelson [28,69] produced RMSEs of 2.75 and  $2.9 \text{ gC/m}^2/\text{day}$ , respectively, by focusing on GCVI and NDVI as predictors. RMSEs between 1 and  $2 \text{ gC/m}^2/\text{day}$  were achieved by incorporating other indices such as the LAI and Wide Dynamic Range Vegetation Index (WDRVI) [27,45]. Our estimation of RMSEs  $< 1 \text{ gC/m}^2/\text{day}$  (Figure 8), across similar ranges of  $\text{GPP}_{\text{in situ}}$ , for the same flux tower sites demonstrates the enhanced accuracy attributable to the machine learning approach encompassing within-season variation.

Our findings demonstrate that varying LUE dynamically over a cropping season will produce more accurate estimates of remotely sensed GPP. Figure 3 shows that  $\text{LUE}_{\text{in situ}}$  varies within seasons, and variables related to seasonality, namely DAS and day length, have been highlighted as important by the random forest model (Figure 5). This is also supported by the partial dependence patterns of the random forest model on DAS, NDVI, and day length (Figures 5 and 6), which reflects patterns identified in Figure 3. Neither the  $\text{LUE}_{\text{max}}$  or stress scalars in CASA account for within-season variation in LUE. We suggest that this source of variation should be a primary component of productivity estimation methods for cropland.

Furthermore, Figure 4 shows that stress scalars did not sufficiently reduce  $\text{LUE}_{\text{max}}$  to reflect  $\text{LUE}_{\text{in situ}}$ , especially for maize. This may be because temperature, vapor, and soil moisture stress did not explain much variation in  $\text{LUE}_{\text{in situ}}$ , though setting  $\text{LUE}_{\text{max}}$  too high also contributed. A weak relationship between the stress scalars and  $\text{LUE}_{\text{in situ}}$  may also explain the poor predictive ability of Model 3 with  $\text{LUE}_{\text{max}}$  as the response (Table 4). This corresponds to Lobell et al. [8] who found greater NPP estimate accuracy with CASA when stress scalars were omitted for irrigated and temperature-resistant crops. They attributed this to the stress scalars being inappropriate indicators of variation in LUE for some croplands where stress may be overcome by either genotypic (temperature stress-resistant cultivars) or agronomic (irrigation) management. Additionally, components of CASA have been criticised for their weak relationship to LUE. Sinclair and Muchow [70] argued that the Occam's Razor philosophy of preferring hypotheses with fewer assumptions should be applied to determining crop LUE in their criticism of relating vapor pressure deficit to LUE. They cited minimal statistical support for a meaningful relationship between these variables. This is supported by our finding that relative humidity was a relatively unimportant predictor of LUE (Figure 5).

Varying LUE within season is specific to remote sensing for croplands because crop maturity and type are generally uniform in space and time within fields, contrasting other land types with heterogeneous vegetation type and age [8]. We have demonstrated that approaches that vary crop LUE primarily on environmental stresses may lack relevance to croplands, and productivity modelling approaches should place more importance on within-season variation. Environmental stress-based approaches may remain applicable to ecological applications where a fixed  $\text{LUE}_{\text{max}}$  reflects a central value for heterogeneous vegetation and plant growth is more greatly influenced by temperature and soil moisture stress [14,17]. However, such approaches may also be enhanced by consideration of diffuse radiation [14,70].

The importance of crop type and predictors relating to within-season variation in the random forest model (Figure 5) show that these variables best reflect the photosynthetic properties of a crop at a given satellite overpass date. The better prediction accuracy, reduced uncertainty, and importance of crop type for Model 1 compared with Model 2 (Table 4 and Figure 5) demonstrate that crop-specific estimates of LUE are greatly preferred. Temporal patterns in GPP and LUE shown in Figure 3 match Lecoecur and Ney's [26]

description of the sigmoidal pattern between LUE and thermal time where LUE reaches a maximum following great variability after emergence, before declining towards zero at the end of the plant growth cycle. The partial dependence plots for LAI, NDVI, and SAVI also show that LUE increases with canopy greenness, corresponding to Gitelson and Gamon's [15] demonstration of a positive relationship between LUE and green LAI found using the US-Ne flux sites (Table 1). Given their relatively important predictive properties (Figure 5), further investigation into the relationships between NDVI, LAI and LUE across crop growth stages would inform how these indices might be used to better predict LUE.

GCVI was the least important of the vegetation indice predictors (Figure 5), despite its hypothetical potential to capture nutrient stress. Figure 6 shows that GCVI values around 0 reduced  $\hat{LUE}$ , which may be due to these values relating to low leaf nitrogen (N) concentration. The relationship between leaf N concentration and LUE has been well described by Sinclair et al. [71,72], Fischer et al. [73], and Evans [74]. Therefore, it has been hypothesised [21] and demonstrated [27] that the GCVI could be an important predictor of LUE given its ability to capture nutrient deficiencies and reflect the photosynthetic capacity of a canopy. Burke and Lobell [21] attributed this ability to their finding that GCVI outperformed NDVI and the Enhanced Vegetation Index (EVI) in prediction of yields at smallholder farms in Kenya. However, Burke and Lobell [21] noted that crop nutrient stress is common in those farming systems. Relatively lower variation in nutrient stress among flux tower sites may explain why the indices related to crop maturity and growth were more important predictors of LUE than the GCVI.

The fixed values for C3 crops produced relatively accurate estimates of GPP compared with the fixed value for C4 maize. This was especially the case for rice. Maize, as a C4 crop, had higher in situ LUE values for these sites, but not to the degree recommended in the setting of  $LUE_{max}$  for PySEBAL and the GYMEE [1,11,12]. The median LUE value of approximately 2.0 gC/MJ for maize from in situ sites (Figure 2) is consistent with Lindquist et al. [75] and Muchow and Sinclair [76]. It is unclear why recommended  $LUE_{max}$  values for maize have become much higher than would give this  $LUE_{CASA}$  in recent times. It may be because these values relate to the true maximum LUE across a growing season and are used to avoid underestimation at high values of GPP. However, our results show that this approach leads to great overestimation of GPP at most time points.

Estimating in situ LUE and  $LUE_{max}$  from inversion of the GPP (Equation (1)) and CASA equations (Equation (2)) leads to some methodological limitations. Optimising the  $LUE_{max}$  parameter is likely to be compensating for some other variable errors, so that our results may reflect overestimation of GPP due to inaccurate estimates of variables such as fPAR and inaccurate quantification of stress scalars. This may also explain some of the poor predictive ability of Model 3 for  $LUE_{max}$  (Table 4). Furthermore, the use of NDVI both as a predictor in the random forest for LUE and the linear equation for fPAR may be confounding. There is also likely to be some error associated with the cropland ecosystem boundary used. More recent flux tower initiatives include data and means to calculate more accurate flux footprints [46,77,78], though few are in croplands with known crop types and agronomic information related to irrigation and fertiliser regimes. Open-source flux tower initiatives in croplands would provide invaluable data for further improving cropland productivity estimates.

Additionally, the increasing abundance and availability of sensors is likely to enable further enhancement of GPP estimation. For example, the relationship between the photochemical reflectance index (PRI) and LUE has been well documented by Gamon et al. [19], Garbulsky et al. [79], and Barton and North [80]. However, narrow-band spectroradiometers are required for its derivation. Future availability of easily deployed and operated unmanned aerial vehicles (UAVs) or other sensors would likely enhance understanding of LUE in croplands.

## 5. Conclusions

The application of crop-specific  $LUE_{max}$  and environmental stress scalars led to over-estimation of GPP for cropland, and this was remedied by varying LUE using a predictive model that captured variation in LUE within seasons. The greater accuracy of GPP estimation means that this predictive model approach is preferable to using CASA for cropland. It also allows quantification of prediction uncertainty, which is especially pertinent where crop type is unknown.

The primary implication of our findings is that the focus of the productivity estimation paradigm for cropland should shift from environmental stress to variation within season and between crop type. Including within-season predictors in models for LUE will enhance the accuracy of GPP estimation and therefore give more accurate measures of derived estimates such as cropland carbon fluxes and crop yields.

## Abbreviations

The following abbreviations are used in this manuscript:

GPP	Gross Primary Productivity
$GPP_{in situ}$	In Situ Gross Primary Productivity
$\hat{GPP}$	Predicted Gross Primary Productivity
NPP	Net Primary Productivity
CASA	Carnegie–Ames–Stanford Approach
LUE	Light Use Efficiency
$LUE_{in situ}$	In Situ Light Use Efficiency
$LUE_{CASA}$	Light Use Efficiency reduced from $LUE_{max}$ Using CASA Stress Scalars
$LUE_{max}$	Maximum Light Use Efficiency
$LUE_{max in situ}$	In Situ Maximum Light Use Efficiency
$\hat{LUE}_{RF}$	Predicted Light Use Efficiency from Random Forest
fPAR	Fraction of Absorbed Photosynthetically Active Radiation
PAR	Photosynthetically Active Radiation
DAS	Days after Sowing
SMS	Soil Moisture Stress
VS	Vapor Stress
TS	Temperature Stress
NDVI	Normalized Difference Vegetation Index

SAVI	Soil-Adjusted Vegetation Index
LAI	Leaf Area Index
GCVI	Green Chlorophyll Vegetation Index
