Review

How the Big Bang Ends Up Inside a Black Hole

Abstract: The standard model of cosmology assumes that our Universe began 14 Gyr (billion years) ago from a singular Big Bang creation. This can explain a vast range of different astrophysical data from a handful of free cosmological parameters. However, we have no direct evidence or fundamental understanding of some key assumptions: Inflation, Dark Matter and Dark Energy. Here we review the idea that cosmic expansion originates instead from gravitational collapse and bounce. The collapse generates a Black Hole (BH) of mass $M \approx 5 \times 10^{22} M_\odot$ that formed 25 Gyrs ago. As there is no pressure support, the cold collapse can continue inside in free fall until it reaches atomic nuclear saturation (GeV), when it is halted by Quantum Mechanics, as two particles cannot occupy the same quantum state. The collapse then bounces like a core-collapse supernovae, producing the Big Bang expansion. Cosmic acceleration results from the BH event horizon. During collapse, perturbations exit the horizon to re-enter during expansion, giving rise to the observed universe without the need for Inflation or Dark Energy. Using Ockham’s razor, this makes the BH Universe (BHU) model more compelling than the standard singular Big Bang creation.

Keywords: cosmology; dark energy; general relativity; black holes

1. Introduction

A cosmological model predicts the evolution of the observed Universe given some initial conditions. The standard cosmological model [1,2], called $\Lambda$CDM, assumes that our Universe expansion began in a hot Big Bang creation at the very beginning of space-time. The $\Lambda$CDM model explains the formation, composition and evolution of our Universe starting from a quantum fluctuation close to Planck scale. Planck scales are so small that space-time itself has to be treated as a quantum object. Such initial conditions violate energy conservation and are very unlikely as they have a low entropy [3,4]. To address such initial conditions properly, we need a new quantum theory of space-time (Quantum Gravity), which opens the door to brane Cosmology [5,6] which is a very exciting idea, but it is hard to test with observations.

Despite these shortfalls, the $\Lambda$CDM model is very successful. However, this is at the cost of introducing three more exotic ingredients or mathematical tricks: Inflation, Dark Matter and Dark Energy, for which we have no direct evidence or understanding at any fundamental level. Are they windows for new discoveries, such as String Theory or new forms of matter/energy, or a signal that the paradigm needs to be replaced? Can we choose some different initial conditions and reproduce the success of the $\Lambda$CDM model without those exotic fixes and within the known laws of Physics?

Here, we present a brief review that summarizes several recent papers [7–13] that suggest a simpler explanation: the Black Hole Universe (BHU). This review also includes some new results and ideas. Some previous studies misinterpreted super horizon scales as scales that were outside the BHU. This is clarified here together with some new details regarding the Big Bounce and the observational interpretation of super horizon perturbations. In Section 2 we give a brief presentation of the $\Lambda$CDM model and its observational support. In Section 3 we present the BHU model using a Newtonian approach. In Cosmology, one can use Newtonian physics to model to a good approximation of both the background and
its perturbations [14]. A consistent Newtonian version of the BHU solution is a good indication that we understand the physics involved. Appendices A and B present a summary of the same BHU solution in the more rigorous GR approach. Appendix C presents some new considerations of the possible effect of rotation in the BHU solution. We end with a Summary and Discussion that includes a review of related literature and previous results and a comparison between models.

2. Observational Evidence for $\Lambda$CDM

We briefly discuss here the main observational evidence of the $\Lambda$CDM, focusing on why exactly it needs those fixes. This review is not exhaustive and does not include all the relevant references. It is just a brief introduction and further work can be found in the references within. We assume flat topology (we will explain why in Section 4).

2.1. The Expansion of the Universe and the FLRW Metric

In 1929, Edwin Hubble published [15] his famous diagram or linear relation (the Hubble law): $\dot{r} = Hr$ relating the radial distance $r$ of 46 galaxies to their radial recession velocity $\dot{r} \simeq zc$, given by the redshift $z$ and the speed of light $c$ ($\dot{r}$ is the time $\tau$ derivative: $\dot{r} \equiv \frac{d}{d\tau}$). Hubble used redshift $z$ from galaxy spectra estimated and published by Vesto Slipher (1917) [16] and Cephid distances $r$ developed by Henrietta Leavitt [17] and calibrated by E. Opik [18]. However, it was George Lemaitre who first understood, in 1927 [19], the meaning of such a discovery [20]: that spacetime is expanding following the new theory of General Relativity (GR) by Albert Einstein [21].

However, you do not actually need GR to figure out the expansion equations. At large scales, the observable Universe looks homogeneous and isotropic. This alone tells us that a physical radial distance $r$ has to scale as $r = a(\tau)\chi$, where $a(\tau)$ is a dimensionless scale factor and $\chi$ is a comoving coordinate, which is fixed ($\chi = 0$) for any comoving observer like us, moving with the expansion. This is the Friedmann–Lemaître–Robertson–Walker (FLRW) metric (i.e., Equation (A1)). The observed expansion law follows from derivation: $\dot{r} = \dot{a}\chi = Hr$ where $H \equiv \dot{a}/a$ is the Hubble expansion rate. Nowadays, $H$ is measured to be $H_0 \simeq 70$ Km/s/Mpc, so a galaxy at $r \simeq 300$ Mpc has a recession velocity of $\dot{r} \simeq zc$ with a redshift $z \simeq 0.07$. The Universe was 7% smaller at the time the light from that galaxy was emitted, $\tau \simeq \frac{1}{2} = 92$ Myr ago. The expansion time is $H_0^{-1} \simeq 14$ Gyr.

Consider a spherically symmetric region of space $r < R$ with a fixed mass $M$ (such as Lemaître model [19]). We can use Gauss law (or the corollary to Birkhoff theorem in GR [22]) to ignore what is outside $R$ so the dynamics of $R$ will be given by the free-fall equation:

$$E = \Phi + K = 0 \Rightarrow K = \frac{1}{2}R^2 = \frac{1}{2}H^2R^2 = -\Phi = \frac{GM}{R} = \frac{4\pi G}{3}\rho R^2. \quad (1)$$

The above equation leads to:

$$r_H^{-2} \equiv H^2(\tau) = \frac{8\pi G}{3}\rho(\tau), \quad (2)$$

which is independent of $R$. This simple Newtonian derivation reproduces exactly the full solution to GR field equations (i.e., Equation (A2)). At any time, the expansion rate $H^2$ is given by $\rho$. In our Universe we have measured their values today ($\rho_0$ and $H_0$) to find that they do so follow: $H_0^2 \simeq 8\pi G\rho_0 / 3$. We use units where the speed of light is $c = 1$, and $r_H \equiv H^{-1}$ is called the Hubble Horizon because it corresponds to an expansion velocity $\dot{r} = Hr$ equal to the speed of light ($r_H = 1$). Energy–Mass conservation requires $\rho \propto a^{-3(1+\omega)}$, where $\omega = \rho / \rho$ is the equation of the state of the fluid: $\omega = 0$ for matter, $\omega = 1/3$ for radiation and $\omega = -1$ for vacuum. Given $a_s = a(\tau_s)$ at some reference time $\tau_s$ and $\tau = 0 = a(0)$, the solution to Equation (2) for one component is:

$$H^2 = H_0^2 \left(\frac{a}{a_s}\right)^{-3(1+\omega)} \Rightarrow a(\tau) = a_s \left[\frac{3(1+\omega)}{2}H_0\tau_s\right]^{\frac{2}{3(1+\omega)}} \Rightarrow r_H = \frac{3(1+\omega)}{2} \tau. \quad (3)$$
During collapse, $H$ and $\tau$ are negative. Note that \( r_H \propto a^{3(1+\omega)/2} \), so for regular matter \((\omega > 0)\), it grows faster than comoving scales: \( \tau = a\chi \) (the opposite is true for \( \omega = -1 \)). Thus, for \( \omega > 0 \) all scales become super horizon \((r > r_H)\) during collapse \((H < 0)\) and re-enter the Hubble horizon during expansion. Note that \( r_H \) increases with time \( \tau \) (like the particle horizon). These equations are the exact solutions to GR for an FLRW metric, where \( \tau \) is the proper time for a comoving observer. Using Equations (2) and (3) we find:

\[
\rho = \frac{[1 + \omega] \tau^2}{6\pi G} \simeq 1.3 \times 10^{-12} \frac{M_\odot}{\text{Km}^3} \left( \frac{(1 + \omega) \tau}{\text{seconds}} \right)^{-2},
\]

which tell us what the density is at any time \( \tau \). In general, \( \rho \) could be made of several components \( \rho_i \): \( \rho = \sum_i \rho_i \), each with different \( \omega_i \). The relative contributions are called cosmological parameters: \( \Omega_i = \rho_i / \rho \), so that \( \sum_i \Omega_i = 1 \). As \( \tau \to 0 \), the matter density becomes very high and the radiation density dominates as temperature increases: \( T = T_0 / a \).

2.2. Nucleosynthesis and CMB

In 1964, Penzias and Wilson [23] accidentally found a uniform Cosmic Microwave Background (CMB) radiation of temperature \( T_0 \simeq 3K \). Robert Dicke, James Peebles, P. G. Roll, and D. T. Wilkinson in the companion publication [24] interpret this radiation as a signature from the hot Big Bang: the oldest light in the Universe. This was first noticed in 1948 by R. Alpher and R. Herman [25,26] who developed the theory of the primordial nucleosynthesis and predicted a leftover CMB radiation of \( T_0 \simeq 5K \), closed to the observed value. The idea behind it is simple. Because the universe is expanding, when you imagine going back in time the density must become higher and higher, atoms will break and the resulting plasma will be dominated by radiation, like the interior of a star. If you simulate an expansion from such initial conditions you can build a prediction for the primordial abundance of elements and radiation that we observed today. This is called primordial nucleosynthesis.

Hydrogen is the most abundant element measured in our Universe. Around \( \sim 75\% \) of the total mass of the atoms (nucleons) in the Universe is in the form of hydrogen, the remaining \( 25\% \) is mostly Helium. The abundance predicted by nucleosynthesis depends on the cross section of several Nuclear Physics reactions, such as neutron capture or decay. These are proportional to the ratio \( \eta = \rho_B / \rho_R \) of the number density of baryons \( \rho_B \) (protons and neutrons) to that of photons, \( \rho_R \), given by the CMB background temperature \( T = T_0 / a \).

So a measurement of the primordial element abundance and \( \rho_B \) can be used to predict \( T_0 \). Nowadays, we use the more precise measured value \( T_0 = 2.726K \) and the observed abundance to predict \( \rho_B \). In relative units: \( \Omega_B = \rho_B / \rho \simeq 0.05 \) [27]. So that only \( \sim 5\% \) of the total energy-density in our Universe is made of regular matter (i.e., made of known baryons and leptons). The rest, according to \( \Lambda \)CDM , is made of Dark Matter and Dark Energy. Where do these numbers come from? Why \( 5\% \) and not \( 20\% \)?

2.3. Cosmic Inflation and the Horizon Problem

Cosmic Inflation [28–31] consists of a period of exponential expansion that must have happened right after the beginning of time \((\tau = 0)\). There are over a hundred versions and variations [2,32], but generically the model requires some hypothetical new scalar field (the inflaton) with negligible kinetic energy \((\omega = -1)\) to dominate the very early universe. After expanding by a factor of \( e^{60} \), inflation leaves the universe empty and we need a mechanism to stop inflation and create the matter and radiation that we observe today. This is called reheating. All these components require some fine tuning and free parameters that are hard to test because the physics involved is beyond reach by experiments [1]. However, Inflation solves some important mysteries that we do not know how to fix otherwise within \( \Lambda \)CDM .

As mentioned below Equation (3), the structures that we observe today were not in causal contact in the past. We say that they are super horizon scales. Structures that are larger than \( r_H \) cannot evolve because the time a perturbation takes to travel that distance is larger than the expansion time. How can these structures form if they were not in causal
contact? This is the horizon problem. A clear evidence of this problem is the uniform CMB temperature across the full sky. The Hubble horizon $r_H$ at CMB times only subtends about one degree in our sky. So causality cannot explain the observed all sky CMB uniformity. The horizon problem is solved by inflation because, during inflation, structures of all scales become a super horizon. After inflation ends, they re-enter the horizon ($\omega = -1$). Moreover, reheating provides a very uniform temperature background at the end of inflation.

2.4. Structure Formation and Dark Matter

In 1992, NASA’s Cosmic Background Explorer (COBE) satellite detected temperature variations of very small relative amplitude $\delta_T \approx 10^{-5}$ in the CMB [33]. We believe those were the seeds that grew under gravitational collapse from to form stars, galaxies and the cosmic web that we observe today. However, where do the seeds come from? Models of Inflation propose that these seeds come from super horizon quantum fluctuations that were exponentially inflated during inflation. Inflation predicts a power law (almost scale invariant) spectrum of fluctuations which agrees with the shape measured by later CMB missions [34–37] and clustering in Galaxy Surveys [38–41]. However, inflation does not provide a specific prediction for $\delta_T \approx 10^{-5}$: it is just a free parameter of the model.

The measured $\delta_T \approx 10^{-5}$ is too small to explain the observed structure in galaxy surveys today [42,43]. Some fix is needed: galaxy bias [44,45] or a $\Lambda$ term [38]. The shape of the spectrum of fluctuations (including the Baryon Acoustic Oscillations, BAO [46–49]) in the CMB and Galaxy Surveys, also required another free component to agree with the $\Lambda$CDM model. They require a new type of matter, that we called Cold Dark Matter (CDM [50]), which is not made of regular matter (baryons) and interacts very weakly with matter or radiation (thus the name). CDM needs to be about four times more abundant than regular matter: $\Omega_{CDM} \approx 4\Omega_B$. Such CDM is also needed to understand the motion of galaxies in clusters [51], the galaxy rotational curves [52], gravitational lensing [53], galaxy evolution [50], cosmic flows [54] and structure in galaxy maps [38–41]. Despite enormous observational efforts in the last 30 yrs, such Dark Matter component has never been directly detected as a real particle or object [55,56].

2.5. Cosmic Acceleration, Dark Energy and the Static Universe

Usually, cosmic acceleration is defined by the adimensional coefficient $q \equiv (\dot{a} / a) H^{-2}$. Taking a derivative of Equation (3) we find $q = -\frac{1}{2}(1 + 3\omega)$. For regular matter we have $\omega > 0$ so we expect the expansion to decelerate ($q < 0$) because of gravity. However, the latest concordant measurements from a Type Ia supernova (SN) [57,58], galaxy clustering [51], the galaxy rotational curves [52], gravitational lensing [53], galaxy evolution [50], cosmic flows [54] and structure in galaxy maps [38–41]. Despite enormous observational efforts in the last 30 yrs, such Dark Matter component has never been directly detected as a real particle or object [55,56].

Dark Energy (DE) was introduced [59] to account for $\omega < 0$. However, there is no fundamental understanding of what DE is or why $\omega \approx -1$. A natural candidate for DE is the cosmological constant $\Lambda$ [60–63], which has $\omega = -1$ and can also be thought of as the ground state of a scalar field (the DE), similar to the Inflaton. $\Lambda$ can also be a fundamental constant in GR, but this has some other complications [61–63]. Including DE in the $\Lambda$CDM model is also needed to complete the energy budget for our Universe: 5% baryons ($\Omega_B \approx 0.05$), 25% Dark Matter ($\Omega_{DM} \approx 0.25$) and 70% DE ($\Omega_\Lambda \approx 0.7$), so that $\Omega_B + \Omega_{DM} + \Omega_\Lambda = 1$, as needed. DE is also important for understanding the Integrated Sachs–Wolfe (ISW) effect [64–67], and to have a longer age estimate of 14 Gyr, which is needed both to account for the oldest stars and to have more time for structures to grow from the small CMB seeds $\delta_T \approx 10^{-5}$ to the amplitude (and shape) we observe today in Galaxy Maps [38,42].

Note how $q = 1$ means $\dot{H} = 0$, so that H becomes constant and all structures become super horizon and freeze, as in Inflation. In the physical or rest frame (see Appendix A.1) this corresponds to a static (deSitter) metric. We are used to repeating that the universe accelerates, but in the limit $q \Rightarrow 1$ it is more physical to say that the universe becomes static, as proposed by Einstein [60] when he introduced $\Lambda$. This can be understood with the Twin
paradox analogy of Special Relativity to explain time dilation. Time happens slower for
the comoving observer according to the physical observer at rest. In the limit of exponential
expansion, time freezers and the expansion stops. Something that is static for the rest frame
observer happens at constant velocity ($H$ constant) for the comoving observer.

3. Inside a Black Hole (BH)

In this section we will first present three different arguments that indicate that our
Universe is inside a BH. This will lead to the BH Universe (BHU) model. How did we end
up inside a BH? We will conjecture a new start for our Universe that could explain both the
Big Bang expansion and why we are inside a BH, without the need to restore to a Quantum
Gravity singularity.

3.1. What Is a BH?

A BH is an object with a radial escape velocity $\dot{R} = c \equiv 1$. The escape velocity $\dot{R}$ is
the minimum one needed to just escape the gravitational pull of a mass $M$. This requires:
$$\frac{1}{2} \dot{R}^2 = \frac{GM}{R}.$$ Thus, for $\dot{R} = c \equiv 1$ we have that $R \equiv r_s = 2GM$, which is called the Event
Horizon. As events cannot travel faster than $c$, nothing can escape from inside $r_s$. Thus we
define a BH as an object of mass $M$ whose radius is:

$$r_s = 2GM \simeq 2.9 \text{ Km} \frac{M}{M_\odot}, \tag{5}$$

so that a solar mass BH has a radius of 2.9 Km. The density of a BH only depends on $r_s$:

$$\rho_{BH} \equiv \frac{M}{V} = \frac{3M}{4\pi r_s^3} = \frac{3r_s^{-2}}{8\pi G} \simeq 9.8 \times 10^{-3} \left( \frac{M_\odot}{M} \right)^2 \frac{M_\odot}{\text{Km}^3}. \tag{6}$$

This value should be compared to the atomic nuclear saturation density:

$$\rho_{NS} \simeq 2 \times 10^{-4} \frac{M_\odot}{\text{Km}^3}, \tag{7}$$

which corresponds to the density of heavy nuclei and results from the Pauli exclusion
principle. For a Neutron Star (NS) with $M \simeq 7 M_\odot$ both densities are the same: $\rho_{BH} = \rho_{NS}$.

This explains why typical NS stars are not larger than $M \simeq 7 M_\odot$, as they could
collapse first into a BH. This is illustrated by Figure 1 which compares the collapse density of a
fix mass cold cloud as a function radius to the density of a BH. Because the star
is collapsing in freefall (assuming no significant pressure support) nothing prevents the
BH to form if the density reaches BH density before it reaches nuclear saturation. The
maximum observed $M$ for NS is closer to $M \simeq 3 M_\odot$ [68] which agrees with more detailed
considerations that include the equation of state estimates.

3.2. Inside a Black Hole

The density of a BH in Equation (6) is the exact density of our Universe in Equation (2)
inside its Hubble Horizon $r_H = 1/H$, as for $R = r_H$, the expansion law gives: $\dot{R} = HR = 1$.
So the Hubble volume around us ($R < r_H$) is causally disconnected from the rest ($R > r_H$)
and has the density of a BH. Very different observations (CMB, SN, BAO, lensing and
LSS) indicate [41] that $H$ tends to a constant $H_\Lambda^2 = H_0^2 \Omega_\Lambda = \frac{8\pi G}{3} \rho_\Lambda$ (i.e., $\omega = -1$) so
the Universe asymptotically becomes static with a fixed radius $(r_\Lambda = H_\Lambda^{-1})$. Nothing can
escape $r_\Lambda$ and the mass inside is given by:

$$M = \frac{4\pi}{3} r_\Lambda^3 \rho_\Lambda = \frac{r_\Lambda}{2G}. \tag{8}$$
i.e., $r_\Lambda = 2GM$. This is the definition of a BH. So we do live inside a BH of mass and size:

$$M \simeq 5 \times 10^{22} M_\odot ; \quad r_S = r_\Lambda = r_H (a = \infty) \simeq 6 \times 10^{22} \text{ km},$$

for $\Omega_\Lambda \simeq 0.7$ and $H_0 \simeq 70 \text{ Km/s/Mpc}$. Figure 2 compares the BHU formation with that of an NS. Inside $r_S \simeq 6 \times 10^{22} \text{ km}$ the density is very low and nothing can stop further collapse. So NS, galaxies and planets could also eventually form inside a BH.

**Figure 1.** Illustration of the collapse of one solar mass ($1 M_\odot$, green dotted line) Neutron Star (NS). As the NS collapses the radius $R$ decreases and the density increases as $R^{-3}$. The collapse stops (bounce back or explodes as a supernova) when the density reaches nuclear saturation $\rho_{ns}$ (green horizontal line). For masses larger that $7 M_\odot$ (red dotted line) the cold cloud collapses first into a BH and matter gets trapped inside the event horizon $r_S$ (black dashed line $R^{-2}$). A NS could collapse inside a larger BH, but it can not escape $r_S$.

**Figure 2.** This is similar to Figure 1 but extending the scale to include a cloud of mass $M = 5 \times 10^{22} M_\odot$ (red dotted line) which corresponds to the size of our Universe.
3.3. The Black Hole Universe (BHU)

An FLRW metric with Λ is inside a trapped surface. The maximum radial distance travel by light (a null geodesic) is:

\[ r_* = a \int_\tau^\infty \frac{d\tau}{a(\tau)} = a \int_a^\infty \frac{d\ln a}{aH(a)} < \frac{1}{H\Lambda} \equiv r_\Lambda. \]  

(10)

As time increase, the Hubble rate becomes constant and \( r_* \) becomes a constant value \( r_* = r_\Lambda \). No signal from inside \( r_* \) can reach outside, similar to in the interior of a BH.

If we use \( r_\Sigma = \frac{2GM}{c} \) in Equation (1) we find:

\[ R = \left[ r_\Sigma^2 r_H \right]^{1/3} \Rightarrow R(\tau) = \frac{3(1+\omega)}{2} \tau^{1/3} \tau^{2/3} = r_\Sigma \left( \frac{a}{a_{BH}} \right)^{1+\omega}, \]

(11)

where \( a_{BH} \) is the scale factor when the BH event horizon is reached. For a regular star \( R > r_\Sigma \) so the expansion is subluminar \( R < r_H \). Our Universe has \( R > r_H \) (we observe super-horizon scales in the CMB) which, using Equation (11), requires \( R < r_\Sigma \). This is a third indication that we are inside our own BH!

For \( \omega = p = 0 \), \( R \) is a time-like geodesic with constant \( \chi = R/a = r_\Sigma/a_{BH} \). For a null geodesic \( R = r_* \) (\( \omega \neq 0 \)) in Equation (10). Equation 11 gives the evolution of a finite FLRW cloud radius \( R(\tau) \). Compared to Equation (3) we can see that \( R \) grows slower than \( r_H \) so perturbations become super-horizon during collapse and re-enter during expansion. So the collapsing phase acts like Inflation. In units of \( r_H \) today \( c/H_0 \equiv 1 \), at CMB times \( a \simeq 10^{-3} \):

\[ r_H \simeq 5 \times 10^{-5}, \text{ while } R \text{ is about 30 times larger}. \]

For constant \( H = H_\Lambda \) we have \( R = r_\Sigma \), which is larger than \( R_0 \) today. Note how for \( R < r_\Sigma \) (i.e., inside the BH) Equation (11) indicates that there is a region with no matter: \( r_\Sigma > R > r_H \) and a region with matter outside the Hubble horizon \( R > r > r_H \). This is illustrated in Figure 3.

Here we have obtained Equations (2) and (11) just using Newtonian Mechanics with the definition of a BH. This is the same solution as the BH Universe (BHU) [10], which is an exact solution to GR and corresponds to an FLRW cloud as in Equation (1). Appendix A presents this same BHU solution within GR.

![Figure 3. Illustration of our Universe inside the event horizon \( r_\Sigma = 2GM \). This is a Schwarzschild (empty) metric outside \( (r > R) \) and an FLRW metric inside \( R \) (red dashed line) with mass \( M \). The Hubble radius \( r_H = c/H \) (dashed line) defines the volume inside causal contact (blue shading) from the center. The BHU solution in Equation (11) requires \( R = \left[ r_\Sigma^2 r_H \right]^{1/3} \), so that \( R \) grows slower than \( r_H \). There is a region with matter outside the Hubble radius \( R > r > r_H \) (yellow shading) with super horizon (or frozen) perturbations. This solves the horizon problem in Cosmology and is a source for perturbations that enter the horizon as the metric expands, creating LSS and BAO in Cosmic Maps, pretty much like what is usually assumed for Cosmic Inflation.](image-url)
3.4. How Did We End Up Inside a BH?

Our Universe must have collapsed to form a BH. Before it collapsed, the density is so small that there are no interactions other than gravity. Even radiation escapes the cloud. The density is still very low when $M$ approaches its corresponding event horizon $R = r_S = 2 \frac{GM}{r_S}$, but the gravitational pull is still that of a BH. Radial comoving shells of matter are in free fall collapse, so they do not feel that pull. This is the Equivalence Principle. So the collapse continuous pass $R = r_S$ inside the BH. We take $\tau_s$ in Equation (3) to correspond to the time $\tau_{BH}$ when $r_H = -r_S$, i.e., FLRW cloud formed a BH:

$$\tau_{BH} = \tau_s = -\frac{2}{3(1 + \omega)} r_S \simeq -11 \text{ Gyrs},$$

(12)

where we have used Equation (9) and $\omega \simeq 0$ (the latest stages of the collapse could have $\omega \simeq 1/3$, but they last a negligible time compare to matter domination). Thus the BH forms 11 Gyr before $\tau = 0$ (the Big Bang) or 25 Gyr ago. The cold collapse continued after the BH formation. In the last stages of the collapse atoms could ionized and part of the energy could transform into heat. This could slow down the collapse. Figure 4 shows the numerical BHU solution using Equations (3) and (11).

Figure 4. Physical coordinate radius $R$ collapsing and expanding as a function of comoving time $\tau$. A spherical cloud of radius $R$ and mass $M$ starts collapsing free-fall under its own gravity. When it reaches $R = r_S = 2 \frac{GM}{r_S}$ it becomes a BH (black sphere). The collapse proceeds inside the BH until it bounces into an expansion (the hot Big Bang). The BH Event Horizon $r_S$ behaves like a cosmological constant with $\Lambda = 3/r_S^2$ so that the expansion freezes before it reaches back to $r_S$. Blue shading ($R < r_H$) indicates causal evolution of radial perturbations. White is approximated as empty space. Super horizon structures in-between $R$ and $r_H$ (yellow shading) are “frozen” and they seed structure formation as they re-enter $r_H$. Contrary to Inflation, the super horizon spectrum of perturbations in the BHU has a cut-off given by $R$.

3.5. The Big Crunch

As mentioned before, there is a region outside the Hubble Horizon $R > r > r_H$ which is dynamically frozen (yellow shading in Figures 3 and 4). This is the source for super horizon perturbations, which can be observed today in the CMB temperature maps. Any small irregularities $\delta \equiv \Delta \rho/\rho$ (such as the particle composition of the fluid) will grow under gravity. This is the so-called gravitational instability. The growth of $\delta$ can start early on within the FLRW cloud, well before $\tau_{BH}$. The amplitude of $\delta$ from gravitational instability is scale invariant [69–71]. In the linear regime, $\delta$ follows a damped harmonic oscillator equation whose solutions [14] are $D_+ \propto a$ and $D_- \propto a^{-3/2}$, which correspond to the growing and decaying mode during expansion. In the collapsing phase the damping
term has a negative sign and fluctuations grow faster with time because $D_-$ is the growing mode when $a$ goes to zero. It is therefore likely that galaxy, stars, planets or life could also form during the collapsing phase. The details might depend on the original FLRW cloud composition. As the cloud collapses and the background density increases, the structures will disappear inside a hot Big Crunch, but the largest scale density perturbations will become super horizon scales (freeze out) and survive the Big Bounce, as they correspond to variations of the background over scales that are causally disconnected.

3.6. The Big Bounce

The energy density $\rho$ in Equation (4) is the same everywhere inside $R$. By $\tau \simeq -10^{-4}$ s, $\rho$ approaches nuclear saturation (GeV) in Equation (7). The radius of our Universe $R$ is close to the distance between Earth and the Sun. However, the Hubble radius is only few Km (containing a few solar masses). So the physical situation is similar to the interior of a regular collapsing star. We conjecture that this leads to a Big Bounce because of the Pauli exclusion principle of Quantum Mechanics. Neutron density is the highest cold density observed in nature. The collapse is halted by neutron degeneracy pressure, causing the implosion to rebound [72]. If the neutron material is elastic enough [73] the collapse could just bounce into an expansion, pretty much like a bouncing of a ball. However, if the expansion rate is too high, the collapse could also led to a supernova (SN) explosion. Global rotation of the FLRW cloud, could slow down the expansion rate (see Appendix C) and play some role in the bounce.

Stars explode as supernovas (SN) either because of runaway nuclear reactions or because of gravitational core-collapse. Protons and neutrons combine and form neutrinos by electron capture. The gravitational potential energy $\Phi$ of the collapse is converted into a neutrino burst. Neutrinos are reabsorbed by the infalling layers producing an SN explosion. For example, the Crab Nebula pulsar in Figure 5 is thought to be a core collapse supernova that exploded releasing a total energy of $10^{51} - 10^{52}$ ergs in the explosion. This energy is very similar to the FLRW collapsed energy of a $M_{\odot}$ star within $r_H \simeq 30$ Km. Recall that the collapse speed is $c$ for $r_H$, so this is also closed to the internal (or rest) energy in Einstein’s most famous equation: $E = M_{\odot}c^2$.

![Figure 5. (Left): The Crab Nebula explosion as observed in 1999 from the Hubble Space Telescope, 945 years after it exploded. A pulsar remnant could be part of the Dark Matter. (Right): the MICE simulation [74] of our expanding Universe. The resulting structures are related in the Big Bounce model.](image)

The bounce is synchronized at different locations because the background density is the same everywhere in the FLRW cloud. The collapse energy is converted into expansion energy ($H > 0$). Neutron stars, small primordial BHs (PBHs) or quark stars [75] could result as remnants of the SN explosions and they could contribute to the Dark Matter that
we see today [76]. The bounce happens at times and energy densities which are many orders of magnitudes away from Inflation or Planck times ($\tau \approx 10^{-35}$ s or $10^{19}$ GeV). So Quantum Gravity is not needed to understand cosmic expansion and there is no monopole problem [29]. This idea needs to be worked out and simulated. Cold nuclear matter at neutron density is a major unsolved problem in modern physics [68], but a Big Bang from a Big Bounce seems more plausible that one that comes out of nothing.

3.7. The Horizon Problem

The farther back we observe an image in the sky, the older it is. The Big Bang, if we could see it, corresponds to a very distant spherical shell in the sky, represented by large red circles in Figure 6. The furthest we can actually see is the CMB shell (dashed circle), which is quite close to $\tau = 0$. This means that $r_H$ (or corresponding comoving particle horizon $\chi_H$) subtends a very small angle in the sky. So no physical mechanism can create the uniform CMB temperature that we see across the full sky. The initial conditions in the Big Bang have to be uniform to start with. This is very unlikely if the Big Bang came out of nothing [3,29]. However, this is exactly what we expect if the Big Bang originates from a uniform Big Bounce. This provides a solution to the Horizon problem without Inflation.

After the Big Bang, the resulting radiation and plasma fluids cool down following the standard FLRW evolution (nucleosynthesis and CMB recombination). The Big Bounce has super horizon irregularities from the collapsing phase which re-enter the horizon $r_H$ as the expansion proceeds. These are the seeds for new structures (BAO and galaxies) that grow under gravitational instability, as illustrated in Figure 5. The key difference with Inflation is that in the BHU the spectrum of incoming fluctuations have a cutoff for scales larger than $\lambda > 2R (k < \pi/R)$, while Inflation is scale invariant in all scales. This results in an anomalous lack of the largest structures in the CMB sky temperature $T$ with respect to the predictions of Inflation. This particular CMB anomaly is well known but is often interpreted in different ways [34,77–80].

A related anomaly is shown in Figure 6. It displays a sky map of relative variations in the fitted values of $\rho_m$ (or cosmological parameter $\Omega_m = \Omega_B + \Omega_{DM} = 1 - \Omega_\Lambda$) over large regions around each position in the sky. There is a characteristic cutoff scale (or causal horizon) shown by grey circles labeled $H_i$. Same horizons are found for different cosmological parameters. This can be interpreted as a detection of super horizon fluctuations from the Big Bounce, with a cutoff given by the size of $H_i$. Similar results were found later by an independent analysis [81]. In Figure 7 we compare the different cutoff scales with the predictions of the BHU. There is a good agreement for both comoving scales $\chi_H$ (left panel) and angular scales. These are independent because only the former depends on the measured values of $H_0$ in each horizon. A recent study of the homogeneity index in the CMB [12] finds a cutoff scale $\Theta_H = 66 \pm 9$ degrees. This is shown as the black symbol in Figure 7 for the mean values of $\Omega_m = 0.3$ and $H_0 = 67$ Km/s/Mpc in the full CMB sky.

3.8. Dark Energy

During the expanding phase we need to include $\Omega_\Lambda$ in the dynamics because the BH Event Horizon $r_S$ forbids anything to escape. This appears in the action of GR as a Gibbons-Hawking-York (GHY) boundary term [82–84], which is equivalent to a $\Lambda$ term when the evolution happens inside an expanding BH (see Appendix B). The measured $\Lambda$ term is the Event Horizon of our BHU in Equation (9). In the standard Big Bang model there is no reason for cosmic acceleration. A new exotic ingredient, Dark Energy (DE), has to be added to account for this new evidence. Moreover, there is no fundamental understanding as to why the DE equation of state $\omega \equiv \rho/p$ should be so close to $\omega = -1$ as found by the latest data compilations [41]. This is instead the natural outcome of the BHU because $\omega = -1$ corresponds to a constant BH Event Horizon $r_S = r_\Lambda$. The expansion freezes and becomes static in the physical frame. For a comoving observer this looks like exponential inflation, but both pictures are equivalent [10,85]. As in the standard cosmological model,
it takes 14 Gyrs to reach now (or $H_0$) from the Big Bounce. So a total of 25 Gyrs from the BH formation in Equation (12).

**Figure 6.** The CMB sky represented as the surface of a sphere (two view angles) whose radius is the distance traveled by the CMB light to reach us (at the center of the sphere). The red circle represents the corresponding spherical surface from the Big Bang light ($\tau = 0$), if we could see it. The CMB particle horizon $\chi \sim r_H$ (small red cones) is the distance travel by light between $\tau = 0$ and $\tau_{CMB}$ and subtends a very small angle in the observed CMB sky. Large grey circles on the CMB surface are therefore super-horizon boundaries (labeled H1, H2 and H3) in the relative variations of cosmological parameters (color scale) at different locations of the CMB sky [9]. Regions $H_i$ correspond to a cutoff in super horizon perturbations (of size $\theta \approx 2R/d_{CMB} \approx 60$ deg) out of the $\tau = 0$ surface. They are inside our BHU, but not causally connected (yellow region in Figure 4).

**Figure 7.** Comparison of the causal horizon $H_i$ sizes shown in Figure 6 and $\theta_H$ from the homogeneity index [12] in comoving $\chi H_0$ and angular units, given the mean measured $\Omega_m$ and $H_0$ in each horizon. This is compared to the BHU predictions ($2R/a$, green), $\chi_6$ [8] (dashed) and $\chi_\Lambda = r_\Lambda/a$ (red) as a function of $\Omega_m$.

**4. Discussion and Conclusions**

Inflation is believed to solve the flatness problem: why our universe has a flat global topology (or geometry) $k = 0$? However, given some matter content, GR can not give us its topology. This is a global property of spacetime that is either assumed or directly measured. The same applies to an intrinsic $\Lambda$ term. Equations (2) and (11) in the BHU are also exact solutions in GR for $k \neq \Lambda \neq 0$ by just replacing $r_H^2 \equiv H^2 + k/a^2 + \Lambda/3$. However, we use $k = \Lambda = 0$ here because these are the values in empty space (for Minkowski metric) and there is no reason, within GR, that they should be different in the presence of matter. So we believe there is no flatness or $\Lambda$ problem that needs to be solved. Such problems only arise when you include other considerations outside GR, for example when you try to explain that the Big Bang could have emerge out of nothing or from Quantum Gravity. Which is not needed in the BHU.

The $\Lambda$CDM model interprets cosmic acceleration as evidence for Dark Energy (or an intrinsic $\Lambda$ term). We have shown instead that this is an indication that we live inside a BH
of mass given by Equation (9). Such interpretation provides a fundamental explanation to the meaning of Λ (see also Appendix B). This results in the BHU solution to GR (see Appendix A), which we have reproduced here in Equation (11) just using simple Newtonian physics. The idea that the universe might be generated from the inside of a BH is not new and has extensive literature [86–91] which mostly focused in deSitter metric for the BH interior. The formation mechanisms involve some modifications or extensions of GR, often motivated by Quantum Gravity or String Theory. The BHU solution is also similar to the Bubble Universe and gravastar solutions [92–97]. However, there are no surface terms (or Bubble) in the BHU and there is regular matter and radiation inside (see Appendix A). Several authors before have proposed that the FLRW metric could be the interior of a BH [98–102]. However, these solutions were incompletely [103] or outside GR. Stuckey [104] showed that a dust filled FLRW metric can be joined to an outside BH metric. This is an independent precursor to the BHU model. Note that the BHU is located within a larger spacetime and is only homogeneous inside the event horizon. We do not know much about the larger spacetime, but it is in principle possible to observe light and matter that comes from outside.

How did our Universe end up inside a BH? If it collapsed to form one, why is it expanding now? As illustrated in Figure 4, the BHU has a mathematical singularity at τ = 0. As we approach that singularity, causal regions become small so the physics involved is similar to that of stars. In nature we have never observed stable cold matter with densities larger than that of an atomic nuclei. We propose here that when the collapsed reaches nuclear saturation density it stops, explodes and bounces back, like a supernova. This is due to the same neutron degeneracy pressure that occurs in NS and atomic nuclei. The time before τ = 0 represents a causal horizon which divides the BHU into smaller solar mass regions that explode and bounce in sync as long as the density is the same. Super-horizon perturbations, produced during the collapse, will be sync out of phase and generate some irregularities. Further work is needed to understand the details and conditions for such Big Bounce to happen and to estimate the perturbations and composition and fraction of compact and diffuse remnants that resulted from the SN explosions.

This provides a uniform start for the Big Bang, solving the horizon problem. The yellow shaded regions in Figures 3 and 4 show that the mass that collapsed into our BHU moved outside the horizon rH. Super-horizon perturbations could seed structure (BAO and galaxies) as they re-enter rH during expansion. The main differences with Inflation is the origin of those perturbations and the existence of a cutoff in the spectrum of fluctuations given by R(τ). As illustrated in Figures 6 and 7, such cutoff has recently been measured in the CMB maps [9,12]. Current and future galaxy surveys are also able to measure this signal [39,105] which could also appear as a dipole [106]. The existence of super horizon perturbations could also be related to the tension in measurements of cosmological parameters from different cosmic scales [107–109] which have similar variations in cosmological parameters [9]. The Big Bounce could also help us understand two remaining mysteries in the ΛCDM paradigm: the origin for the amplitude δT ≃ 10^-5 in the CMB and the nature of Dark Matter. Structure formation during the collapse and bounce could be key to understand them. Compact remnants such as BHs or neutron could also be detected and account for all Dark Matter. In Appendix C we give some simple considerations on the role of BH rotation. These ideas requires further work and validation. Table 1 presents a comparison of ΛCDM and BHU solutions.

The BHU solution can also be used to understand the interior of a BH. This sounds similar to Smolin [102], who speculated that all final (e.g., BH) singularities ‘bounce’ or tunnel to initial singularities of new universes. However, the bounce proposed here, based on Pauli exclusion principle in Quantum Mechanics, could avoid both the BH and the Big Bang mathematical singularity theorems [110,111]. That a non singular version of such solutions exist is clear from direct observation of stars and BHs. As stated by Ellis [112], the concept of physical infinity is not a scientific one.

The Big Bounce proposed here, based in Quantum Mechanics, could avoid both the BH and the Big Bang singularities [110,111]. The BHU also eludes the entropy paradox [3] in a similar way as that proposed by Penrose [4]. The difference is that the BHU does not require new laws (infinite conformal re-scaling) or cyclic repetition. Our Universe will end up trapped, static and frozen, just as first modeled by Einstein in 1917 [60] when he introduced $\Lambda$. However, we have found here that $\Lambda$ is just the Event Horizon of our BHU and therefore of a larger and older background which could contain many other BHUs.

**Appendix A. Exact solution in General Relativity**

The flat FLRW metric in comoving coordinates $\xi^a = (\tau, \chi, \theta, \delta)$, corresponds to an homogeneous and isotropic space:

$$ds^2 = f_{\alpha\beta}d\xi^\alpha d\xi^\beta = -d\tau^2 + a(\tau)^2 \left[ d\chi^2 + \chi^2 d\Omega \right],$$  \hspace{1cm} (A1)

where we have introduced the solid angle: $d\Omega^2 = d\theta^2 + \sin^2 \theta d\phi^2$. The scale factor, $a(\tau)$, describes the expansion/contraction as a function of comoving or cosmic time $\tau$ (proper time for a comoving observer). For a perfect fluid Equation (A24) with density $\rho$ and pressure $p$, the solution to Einstein’s field equations Equation (A23) is well known [113]:

$$H^2 \equiv \left( \frac{\dot{a}}{a} \right)^2 = \frac{8\pi G}{3} \rho = H_0^2 \left[ \Omega_m a^{-3} + \Omega_R a^{-4} + \Omega_\Lambda \right]$$ \hspace{1cm} (A2)

$$\rho_\Lambda \equiv \rho_{\text{vac}} + \frac{\Lambda}{8\pi G} \; ; \; \rho_c \equiv \frac{3H^2}{8\pi G} \; ; \; \Omega_X \equiv \frac{\rho_X}{\rho_c(a = 1)},$$ \hspace{1cm} (A3)

where $\Omega_m$ (or $\rho_m$) represent the matter density today ($a = 1$), $\Omega_R$ is the radiation, $\rho_{\text{vac}}$ represents vacuum energy: $\rho_{\text{vac}} = -p_{\text{vac}} = V(\phi)$ and $\rho_\Lambda = -p_\Lambda$ is the effective cosmological constant density. Note that $\Lambda$ (the raw value) is always constant, but $\rho_\Lambda$ (effective
value) can change if \( \rho_{\text{vac}} \) changes. Given \( \rho(\tau) \) and \( p(\tau) \) we can use the above equations to find \( a(\tau) \).

Consider next the most general form of a metric with spherical symmetry in physical or Schwarzschild (SW) coordinates \((t, r, \theta, \varphi)\) [1,113]:

\[
\text{ds}^2 = g_{\mu\nu}dx^\mu dx^\nu = -(1 + 2\Psi)dt^2 + \frac{dr^2}{1 + 2\Phi} + r^2d\Omega^2,
\]

where \( \Phi = \Phi(t, r) \) and \( \Psi = \Phi(t, r) \) are the generic gravitational potentials. The Weyl potential \( \Phi_W \) is the geometric mean of the two:

\[
(1 + 2\Phi_W)^2 = (1 + 2\Phi)(1 + 2\Psi).
\]

\( \Psi \) describes propagation of non-relativist particles and \( \Phi_W \) the propagation of light. The solution to Einstein’s field equations Equation (A23) for empty space \((\rho = p = \rho_\Lambda = 0)\) results in the Schwarzschild (SW) metric:

\[
2\Phi = 2\Psi = -2GM/r \equiv -r_S/r,
\]

which describes a singular BH of mass \( M \) at \( r = 0 \). The solution for \( \rho = p = M = 0 \), but \( \rho_\Lambda \neq 0 \) results in deSitter (dS) metric:

\[
2\Phi = 2\Psi = -r^2/r_\Lambda^2 \equiv -r^2H_\Lambda^2 = -r^28\pi G\rho_\Lambda/3.
\]

We also consider a generalization of the dS metric, which we call a dS extension (dSE), which is just a recast of the general case:

\[
2\Phi(t, r) \equiv -r^2H^2(t, r) \equiv -r^2/r_H^2,
\]

and arbitrary \( \Psi \).

**Appendix A.1. Dual Frame: FLRW in the Physical Frame**

Consider a change of variables from \( x^\mu = [t, r] \) to comoving coordinates \( \xi^\nu = [r, \chi] \), where \( r = a(\tau)\chi \) and angular variables \((\theta, \delta)\) remain the same. The metric \( g_{\mu\nu} \) in Equation (A4) transforms to \( f_{a\dot{a}} = \Lambda_{a}^{\mu}\Lambda_{\dot{a}\mu}g_{\mu\nu} \), with \( \Lambda_{a}^{\mu} \equiv \frac{\partial x^\mu}{\partial \xi^a} \). If we use:

\[
\Lambda = \left( \begin{array}{c}
\frac{\partial t}{\partial \tau} & \frac{\partial t}{\partial \chi} \\
\frac{\partial r}{\partial \tau} & \frac{\partial r}{\partial \chi}
\end{array} \right) = \left( \begin{array}{c}
(1 + 2\Phi_W)^{-1} & \frac{aH(1 + 2\Phi_W)^{-1}}{rH} \\
0 & (1 + 2\Phi)^{-1}
\end{array} \right)
\]

with \( 2\Phi = -r^2H^2 \) and arbitrary \( a(\tau) \) and \( \Psi \), we find:

\[
f_{a\dot{a}} = \Lambda^T \left( \begin{array}{c}
-(1 + 2\Psi) & 0 \\
0 & (1 + 2\Phi)^{-1}
\end{array} \right) \Lambda = \left( \begin{array}{c}
-1 & 0 \\
0 & a^2.
\end{array} \right)
\]

In other words, these two metrics are the same:

\[
-(1 + 2\Psi)dt^2 + \frac{dr^2}{1 - r^2H^2} = -d\tau^2 + a^2d\chi^2.
\]

The dSE metric in Equation (A8) with \( 2\Phi = -r^2H^2 \) corresponds to the FLRW metric with \( H(t, r) = H(\tau) \): this is a hypersphere of radius \( r_H \) that tends to \( r_\Lambda \) (see bottom left panel in Figure A1). This frame duality can be understood as a Lorentz contraction \( \gamma = 1/\sqrt{1 - u^2} \) where the velocity \( u = \dot{r} \) is given by the expansion law: \( \dot{r} = Hr \). An observer in the SW frame, not moving with the fluid, sees the moving fluid element \( ad\chi \) contracted by the Lorentz factor \( \gamma: a\dot{\chi} \Rightarrow \gamma d\tau. \)
Figure A1. Representation of $ds^2 = (1 + 2\Phi)^{-1}dr^2 + r^2d\Omega^2$ in polar coordinates embedded in 3D flat space. Yellow region shows the 2D projection coverage in the true $(x,y)$ plane. In (bottom left) we show: deSitter (dS, $2\Phi = -r^2/r^2_\Sigma$) and FLRW ($r = r(\tau) < r_\Sigma$, blue sphere inside dS). In (top left), we show Schwarzschild (SW, $2\Phi = -r_\Sigma/r$). In the (top right), we show a BHU with dS (or FLRW) interior and SW exterior. More generally, the BHU solution has two nested FLRW metrics join by SW metric (bottom right).

Appendix A.2. The BHU Solution

We next look for solutions where we have matter $\rho_m = \rho_m(t,r)$ and radiation $\rho_R = \rho_R(t,r)$ inside some radius $R$ and empty space outside:

$$\rho(t,r) = \begin{cases} 0 & \text{for } r > R \\ \rho_m + \rho_R & \text{for } r < R \end{cases}.$$  \hspace{1cm} (A12)

When $R > r_\Sigma$, we call this an FLRW cloud and when $R < r_\Sigma$ this is a BH Universe. For $r > R$, we have the SW metric. For the interior we use the dSE notation in Equation (A8):

$$2\Phi(t,r) \equiv -r^2H^2(t,r) \equiv -r^2/r_\Sigma^2,$$

so that:

$$2\Phi(t,r) = \begin{cases} -r_\Sigma/r & \text{for } r > R \\ -r^2H^2 & \text{for } r < R \end{cases}.$$  \hspace{1cm} (A13)

At the junction $r = R$, we reproduce Equation (11). For $r < R$, we can change variables as in Equations (A9)–(A11). In the comoving frame of Equation (A11), from every point inside de BHU, comoving observers will have the illusion of an homogeneous and isotropic space-time around them, with a fixed Hubble–Lemaître expansion $H(\tau)$. This converts dSE metric into FLRW metric. So the solution is $H(t,r) = H(\tau)$ and $R(\tau) = [r_\Sigma/H^2(\tau)]^{1/3}$. Given $\rho(\tau)$ and $p(\tau)$ in the interior we can use Equation (A2) to find $H(\tau)$ and $R(\tau)$:

$$H^2(\tau) = \frac{8\pi G}{3}\rho(\tau) = \frac{r_\Sigma}{R^3(\tau)}.$$  \hspace{1cm} (A14)

This corresponds to a homogeneous FLRW cloud of fix mass $M = r_\Sigma/2G$ in Equations (2) and (11). This solution exist for any content inside $R$ [10]. Figure A1 shows a spatial representation of the SW, dS, FLRW and BHU solutions.
Appendix A.3. Junction Conditions

We can arrive at the same BHU solution using Israel’s junction conditions [114,115]. We can combine two solutions with different energy content, as in Equation (A12), to find a new solution. To do that we need to find a hypersurface junction $\Sigma$ to match them well. In our case, this will be given by $R$. The junction conditions require that the metric and its derivative (the extrinsic curvature $K$) match at $\Sigma$. The join metric then provides a new solution to GR. In many cases, like in the Bubble Universes or gravastar [92–97], which match dS and SW metric, this does not work and the junction requires a surface term (the bubble) to glue both solutions together. For the BHU there are no surface terms [10], which shows that this is an exact solution. In the limit where the FLRW has constant $H$ (i.e., our future), the BHU solution corresponds to match between dS and SW metric. So a Bubble Universe without bubble.

To see this, consider the case where $\Sigma$ is given by $R$ in the freefall collapse of an FLRW cloud of fixed mass $M$. For matter domination, this corresponds to $R = a(\tau)\chi_s$ as in Equation (11), where $\chi_s = r_s/a_{BH}$ is fixed. The induced 3D metric on $\Sigma$ is $h^\pm_{\alpha\beta}$ with coordinates $dy^\alpha = (d\tau, d\delta, d\theta)$:

$$ds^2_{\Sigma^-} = h^-_{\alpha\beta}dy^\alpha dy^\beta = -d\tau^2 + a^2(\tau)\chi_s^2 d\Omega^2.$$  \hfill (A15)

For the outside SW frame, the junction $\Sigma^+$ is described by $r = R(\tau)$ and $t = T(\tau)$, where $\tau$ is the FLRW comoving time and $t$ the time in the physical frame. We then have:

$$dr = \dot{R}d\tau ; \quad dt = \dot{T}d\tau,$$  \hfill (A16)

where the dot refers to derivatives with respect to $\tau$. The metric $h^+$ induced in the outside SW metric is:

$$ds^2_{\Sigma^+} = h^+_{\alpha\beta}dy^\alpha dy^\beta = -Fd\tau^2 + \frac{dr^2}{F} + r^2 d\Omega^2$$

$$= -(FT^2 - R^2/F)d\tau^2 + R^2 d\Omega^2,$$  \hfill (A17)

where $F \equiv 1 - r_s/R$. Comparing Equation (A15) with Equation (A17), the first matching conditions $h^- = h^+$ are then:

$$R(\tau) = a(\tau)\chi_s ; \quad FT = \sqrt{R^2 + F} \equiv \beta(R, R).$$  \hfill (A18)

For any given $a(\tau)$ and $\chi_s$, we can find both $R(\tau)$ and $\beta(\tau)$. We also want the derivative of the metric to be continuous at $\Sigma$. For this, we estimate the extrinsic curvature $K^\pm$ normal to $\Sigma^\pm$ from each side of the hypersurface:

$$K_{\alpha\beta} = -[\partial_{\alpha}n_\beta - n_\xi \Gamma^\xi_{\alpha\beta}]e^\xi_a e^b_\beta,$$  \hfill (A19)

where $e^a_\alpha = \partial x^a / \partial y^\alpha$ and $n_a$ is the 4D vector normal to $\Sigma$. The outward 4D velocity is $u^a = e^\alpha_\tau = (1, 0, 0, 0)$ and the normal to $\Sigma^-$ on the inside is then $n^- = (0, a, 0, 0)$. On the outside $u^a = (T, R, 0, 0)$ and $n^+ = (-R, T, 0, 0)$. It is straightforward to verify that: $n_a u^a = 0$ and $n_a n^a = +1$ (for a timelike surface) for both $n^-$ and $n^+$. We then find that the extrinsic curvature in Equation (A19) to the $\Sigma$ junction, estimated with the inside FLRW metric, i.e., $K^-$ is:

$$K^-_{\tau\tau} = -[\partial_{\tau}n^-_\tau - a\Gamma^\tau_{\tau\tau}]e^\tau_\tau e^\tau_\tau = 0$$

$$K^-_{\delta\theta} = a\Gamma^\delta_{\tau\delta} e^\tau_\delta e^\tau_\theta = -a\chi_s = -R.$$  \hfill (A20)

For the SW metric:
\[ K^+_{\tau\tau} = \dot{R}^2 - \dot{R}^2 + \frac{Tr_S}{2R^2}(T^2F^2 - 3\dot{R}^2) = \frac{\dot{\beta}}{R} \]

\[ K^+_{\theta\theta} = TT^\theta_\theta = -TR = -\beta R, \quad (A21) \]

where we have used the definition of \( \beta \) in Equation (A18). In both cases \( K_{\delta\delta} = \sin^2 \theta K_{\delta\delta}, \) so that when \( K_{\theta\theta} = K_{\theta\theta}^+ \) it follows that \( K_{\delta\delta} = K_{\delta\delta}^+ \). Comparing Equation (A20) with Equation (A21), the matching conditions \( K_{\alpha\beta}^+ = K_{\alpha\beta}^+ \) require \( \beta = 1 \), which using Equation (A18) gives: \( R = \left[r_1F_S\right]^{1/3} \). This reproduces the junction in Equation (11). So the two metrics and derivatives (the extrinsic curvature) are identical in the hypersurface defined by \( R \). This completes the proof that the FLRW cloud is an exact solution of GR without surface terms. For more details see [10].

**Appendix B. The Action of GR and the \( \Lambda \) term**

Consider the Einstein–Hilbert action [113,116]:

\[ S = \int_{V_4} dV_4 \frac{\left[R - 2\Lambda/16\pi G \right]}{16\pi G} + L, \quad (A22) \]

where \( dV_4 = \sqrt{-g}d^4x \) is the invariant volume element, \( V_4 \) is the volume of the 4D spacetime manifold, \( R = R^\mu_\mu \) is the Ricci scalar curvature and \( L \) the Lagrangian of the energy-matter content. We can obtain Einstein’s field equations (EFE) for the metric field \( g_{\mu\nu} \) from this action by requiring \( S \) to be stationary \( \delta S = 0 \) under arbitrary variations of the metric \( \delta g^{\mu\nu} \). The solution is [21,113]:

\[ G_{\mu\nu} + \Lambda g_{\mu\nu} = 8\pi G T_{\mu\nu} \equiv -\frac{16\pi G}{\sqrt{-g}} \delta(\sqrt{-g}L), \quad (A23) \]

where \( G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R \). For perfect fluid in spherical coordinates:

\[ T_{\mu\nu} = (\rho + p)u_\mu u_\nu + pg_{\mu\nu}, \quad (A24) \]

where \( \rho \) and \( p \) are the energy-matter density and pressure. This fluid can be made of several components, each with a different equation of state \( p = \omega \rho \).

Equation (A23) requires that boundary terms vanish (e.g., see [113,117]). If there are boundaries to the dynamic equations, we need to add a Gibbons-Hawking-York (GHY) boundary term [82–84] to the action in Equation (A22):

\[ S_{GHY} = \frac{1}{8\pi G} \int_{\partial V_4} d^3 y \sqrt{-h} K, \quad (A25) \]

so that the total action is \( S + S_{GHY} \) and \( K \) is the trace of the extrinsic curvature at the boundary \( \partial V_4 \) and \( h \) is the induced metric. The expansion that happens inside an isolated BH is bounded by its event horizon \( r < r_S \) and we need to add the GHY boundary term \( S_{GHY} \). The integral is over the induced metric at \( \partial V_4 \), which for a time-like junction \( d\chi = 0 \) corresponds to \( R = r_S \):

\[ ds^2_{\partial V_4} = h_{\alpha\beta}dy^\alpha dy^\beta = -d\tau^2 + r_S^2d\Omega^2. \quad (A26) \]

So the only remaining degrees of freedom in the action are time \( \tau \) and the angular coordinates. We can use this metric and the trace of the extrinsic curvature at \( R = r_S \) to estimate \( K = -2/r_S \) from Equation (A20). This result is also valid for a null geodesic [10]. We then have:

\[ S_{GHY} = \frac{1}{8\pi G} \int d\tau 4\pi r_S^2 K = -\frac{r_S}{G} \tau. \quad (A27) \]

The \( \Lambda \) contribution to the action in Equation (A22) is: \( S_{\Lambda} = -\Lambda V_4/(8\pi G) = -r_S^3\Lambda \tau / 3G \), where we have estimated the total 4D volume \( V_4 \) as that bounded by \( \partial V_4 \) inside \( r < r_S \).
i.e., $V_4 = 2V_3\tau$, where the factor 2 accounts for the fact that $V_3 = 4\pi r_3^2 / 3$ is covered twice, first during collapse and again during expansion. Comparing the two terms we can see that we need $\Lambda = 3\pi < 0$ or equivalently $r_\Lambda = r_5$ to cancel the boundary term. In other words: expansion inside a BH event horizon induces an effective $\Lambda$ term in the EFE even when there is no $\Lambda$ background term to start with. Such event horizon becomes a boundary for outgoing geodesics, i.e., expanding solutions. This provides a fundamental interpretation of the observed $\Lambda$ as a causal boundary [7,8,11].

Appendix C. Outside Our BHU: A Rotating Cloud

If the FLRW cloud is not totally isolated it could have some rotation. This could be a way to infer if there is something outside our BHU. Any rotation, no matter how small, could prevent or interfere with the cloud collapse. Can we detect such rotation? A rotating BH is a bit more difficult to model because spherical symmetry is lost and the BH becomes oblate (i.e., the Kerr metric [118]):

$$x = \sqrt{r^2 + r_1^2 \sin \theta \cos \Phi}; \quad y = \sqrt{r^2 + r_1^2 \sin \theta \cos \Phi}; \quad z = r \cos \theta,$$

where $r_1 = J / M$ is the ratio between the angular momentum $J$ and the BH mass. A detailed analysis of this case is outside the scope of this review, but we will make some energy considerations to understand the possible impact of such rotation on the Big Bounce. We assume that both mass $M$ and angular momentum $J$ are conserved, so $r_1$ is constant. We also assume that $r_1 \ll r_5$ so during the collapse we can neglect deviations from spherical symmetry. If we start from the FLRW cloud of size $R$ and mass $M$ with some small initial rotation, $\dot{\theta}$, these products have to be constant:

$$J/M = r_1 = R^2 \dot{\theta} = r_5 \dot{\theta}_{BH}.$$  \hspace{1cm} (A29)

As $R$ gets smaller, $\dot{\theta}$ will become larger. The kinetic energy term in Equation (1) will have another contribution $2K = R^2 \ddot{\theta}^2 R^2$, so that Equation (2) becomes:

$$r_H^{-2} \equiv H^2(\tau) = \frac{8\pi G}{3} \rho(\tau) - r_1^2 \left( \frac{a}{a_{BH}} \right)^{-3(1+\omega)} - r_5^2 \left( \frac{a}{a_{BH}} \right)^{-4(1+\omega)},$$ \hspace{1cm} (A30)

where in the last step we have used Equations (3) and (11) for a collapsing FLRW cloud with equation of state $\omega$. So, for $\omega = 0$, rotation acts like a radiation term of negative energy density. Rotation is negligible, except when $a \to 0$ when rotation tends to delay the collapse, as it reduces the expansion rate $H$. Unless angular momentum is lost some other way, the rotation component will dominate (stop the collapse) for:

$$r_1 \simeq r_5 \left( \frac{a}{a_{BH}} \right)^{(1+\omega)/2}.$$ \hspace{1cm} (A31)

Close to the Big Bounce, if radiation dominates ($\omega = 1/3$) with neutron energy densities (GeV), we have $a \simeq 10^{-12}a_{BH}$. So the condition for the rotation not to interfere with the collapse is:

$$r_1 \ll 10^{-8}r_5.$$ \hspace{1cm} (A32)

Equivalently, as $r_5 \simeq H_0^{-1}$, see Equation (9), $\dot{\theta}_{BH}$ in Equation (A29) has to be:

$$\dot{\theta}_{BH} \ll 10^{-8} H_0,$$ \hspace{1cm} (A33)

so less than $10^{-8}$ cycles per Hubble time. Such a small contribution is undetectable in today’s expansion law: $\Omega_1 \simeq 10^{-16}$ in Equation (A30), or during recombination, but it could be bounded using nucleosynthesis or by its affects on the Big Bounce.
